# 1. Introduction

## 1.1 Structure and Function of the Mammalian Retina

The eye is the optical camera of the body which transmits and focuses light onto a complex highly-structured neuronal tissue called the retina. The retina is located in the proximal segment of the eye and is the first station of the neuronal visual system (Fig 1A). The mammalian retina allows for the perception of color, shape and motion through complex signaling pathways which are ultimately amplified and extracted before being transmitted to the midbrain and thalamus via the optic nerves. Signal processing is carried out by five main classes of retinal cells which are segregated into alternate, anatomically distinctive layers (Fig 1B): photoreceptors, bipolar cells, amacrine cells, horizontal cells and ganglion cells (Fig 1C) (Sung and Chuang, 2010).

**Figure 1. Gross anatomy of the eye ball and detailed cross-section of the human retina.** A. The retina lines the back of the eye ball. B. Stained cross-section of the retina highlighting the different layers of the retina. RPE: retinal pigment epithelium, OS: outer segment, IS: inner segment, ONL: outer nuclear layer, OPL: outer plexiform layer, INL: inner nuclear layer, IPL: inner plexiform layer, GCL: ganglion cell layer. C. Schematic overview of the organization of the retinal cells. R: rod, C: cones, H: horizontal cells, B: bipolar cells, A: amacrine cells, M: Müller cells, G: ganglion cell. Eye ball adapted from: <http://sparemed.blogspot.de/2011/05/good-vs-bad-eyeball.html> Retinal cross section modified from: <http://pathology.wustl.edu/research/corbolab/projects.htm> Schematic diagram of retinal cells adapted from Sung and Chuang, 2010

Visual perception begins when light crosses the retina, which is approximately 0.2mm in thickness, and reaches the light-sensitive photoreceptor cells (Yau and Hardie, 2009). The retina contains two type of photoreceptor cells: rods and cones. In humans, the cone-photoreceptors are

specialized in day- and color vision and enriched in fovea, whereas rod photoreceptors mediate vision in dim light and are located predominantly in peripheral areas of the retina. The human retina contains approximately 110 million rod- and 6 million cone-photoreceptors (Klinke and Toth, 2003). The photoreceptors are juxtaposed to the outermost layer of the retinal pigment epithelium (RPE) which is known to play a critical role in their regeneration. The RPE is responsible for the maintenance of retinal homeostasis, the formation of the outer blood-retinal barrier and absorption of scattered or unabsorbed light. RPE cells also phagocytose membranous discs which are shed by photoreceptor outer segments (Dunn et al., 1996), recycle the light sensitive pigment rhodopsin and provide nutrients to the photoreceptors. The nuclei of the photoreceptors constitute the tightly packed outer nuclear layer (ONL) which are connected to the outer segments (OS) by the connecting cilium (Horst et al., 1990). Visual perception begins when the chromophore conjugated with opsin, absorbs a photon in the OS of a photoreceptor. The photo-excited visual pigment initiates a signal transduction cascade which leads to the closure of cation channels and results in a hyperpolarisation of the cell membrane. This photo-transmission is forwarded to inner retinal cells such as the horizontal or bipolar cells via synapses in the outer plexiform layer (OPL). The cell bodies of the inner retinal cells are found in the inner nuclear layer (INL). Signals from the inner retinal cells are further relayed to the ganglion cells in the ganglion cell layer (GCL) via synapses found in the inner plexiform layer (IPL) (Sung and Chuang, 2010). Amacrine cells in the INL laterally modify signals from the horizontal cells to the ganglion cells, whose axons build the optic nerve which further transmits information to the midbrain (Masland, 1988). Between the stratified layers of the retina exist two other cell types which are important for the maintenance and health of the retina: the Müller glia cells and microglia cells.

## 1.2 Müller Cells

Astrocytes are macroglia which are found in the brain in various forms, with one form existing in the mammalian retina called Müller cells (Reichenbach and Bringmann, 2010). Müller cells are specialized radial glial cells which span the entire thickness of the retina in columns contacting all retinal neuronal somas and processes (Bringmann et al., 2006). This anatomical link is important for information processing as well as neuronal survival. Among many other roles, Müller cells maintain the structural stability of the retina, regulate extracellular homeostasis of relevant ions, remove metabolic waste and metabolize glucose to lactate which is preferentially taken up by photoreceptors as a fuel for their oxidative metabolism (Poitry-Yamate et al., 1995; Newman and

Reichenbach, 1996). Müller cells can also modulate immune and inflammatory responses and buffer mechanical deformations of the retina tissue (Lu et al., 2006; Bringmann et al., 2009; Reichenbach and Bringmann, 2010). However, the main cell type which modulate immune and inflammatory responses are the microglia.

## **1.3 Microglia cells**

In contrast to macroglia cells which arise from primitive neuroepithelium together with neurons, microglia originate from myeloid precursors in the yolk sac during very early embryonic development before the formation of the blood brain barrier (Ginhoux et al., 2010). Like macrophages, microglia are mononuclear phagocytes and act as the resident immune cells of the central nervous system (CNS) (Kreutzberg, 1996). They make up 10% of total glial population in the CNS, are found ubiquitously and serve as sensors and executors of innate immunity within the CNS (Vaughan and Peters, 1974; Graeber and Streit, 2001).

### **1.3.1 Microglia in the CNS and Retina**

Microglia cells were first described by Del Rio Hortega in 1919 as unique cells in the CNS with an elongated soma bearing processes extending from both poles of the cell (Del Rio Hortega, 1919). This phenotype is termed as ramified microglia. In this form, microglia are able to scan the environment using their processes allowing them to quickly identify changes or injuries in tissues (Raivich, 2005). Moreover, the highly motile microglial ramifications have been shown to continuously scan the CNS microenvironment with estimates that the complete brain parenchyma is monitored every few hours (Davalos et al., 2005; Nimmerjahn et al., 2005). Depending on their location in the CNS, microglia can have major morphological differences with regard to the size and orientation of their ramifications. The density of microglial cells also seems to be determined by region-specific cues. Such heterogeneity of microglia density and morphology might be linked to functional heterogeneity of microglia (Davoust et al., 2008). In the adult retina, microglia are normally found in the OPL and IPL (Hume and Gordon, 1983) at the margin adjacent to the nuclear layers (Ebert et al., 2009; Karlstetter et al., 2010). From their location in the brain and retina, microglia can assess the homeostatic state of the tissue and carry out their functions.

### 1.3.2 Function of the Microglia Cells

Microglia cells exert many physiological functions in the developing and adult CNS. These include the induction of apoptosis in specific subpopulations of developing neurons, the control of synaptogenesis, the synthesis of neurotrophic factors and the regulation of synaptic transmissions (Elkabes et al., 1996; Marin-Teva et al., 2004; Roumier et al., 2004; Coull et al., 2005). In order to carry out their function to maximum efficiency, microglia exist individually and keep their distance from one another while covering their own surveillance territory. This microglia immune network is different from other neuroglia which have established syncytial networks (Graeber, 2010). It is therefore likely that microglia communicate using auto- and paracrine mechanisms (Liu et al., 2009).

Microglia also communicate with neurons which signal microglia about their status via use of different ligands, neurotransmitters and neurotrophins (Kettenmann et al., 1990; Biber et al., 2007; Pocock and Kettenmann, 2007). Two characterized ligands, CD200 and CX3CL1 (CX3C chemokine ligand 1, also known as fractalkine), which are found to be constitutively expressed on the neuronal membrane surface have their corresponding receptors, CD200R and CX3CR1, expressed on microglial surface (Hoek et al., 2000; Biber et al., 2006). Signals between aforementioned ligands and receptors provide suppressive signals to microglia, preventing harmful activation as well as maintenance of homeostatic state (Carter and Dick, 2004; Cardona et al., 2006). Furthermore, CD200 and CX3CL1 stimulate microglia migration and protrusion movements, controlling surveillance frequency and vigilance in healthy tissues (Carter and Dick, 2004). However, upon detection of injury or subtle alterations in their microenvironment, such as imbalances in ion homeostasis, microglia cells undergo morphological changes and enter an 'active' state (Kettenmann et al., 1990).

### 1.3.3 Activation and Morphological Plasticity of Microglia Cells

One of the most remarkable features of microglia is their high level of morphological and functional plasticity in response to activating stimuli. Under a number of pathological conditions, ramified microglia will activate and undergo a graded morphological transformation resulting in shorter, thicker processes and larger soma size (Kreutzberg, 1996). By the end of such a process, fully activated microglia, also called reactive microglia, harbor a similar morphology to activated macrophages (Fig 2). Microglia become more motile and actively move to site of injury as well as

increase in local density, either by *in situ* proliferation or recruitment of myeloid cells from the blood stream. This results in a greater defense system of the tissue which can protect and restore tissue homeostasis (Xu et al., 2007; Soulet and Rivest, 2008; Graeber, 2010).

**Figure 2. Microglia activation occurs in a graded manner.** On the left: Ramified microglia are thin with protrusion extending from both poles of the cell. Upon alterations in the microenvironment, microglia undergo graded morphological changes including thicker somas, shorter protrusions, smaller cell size, rounded amoeboid cell shape with short thick protrusions and finally a fully phagocytic activated cell. Adapted from Kreutzberg, 1996.

Activated microglia are found to exert functions commonly assigned to all tissue-resident macrophages under inflammatory conditions. These include notably phagocytosis, antigen presentation and secretion of pro-inflammatory cytokines such as interleukin (IL)-6, IL-1 or tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), as well as reactive oxygen intermediates and nitric oxide (Banati et al., 1993; Bauer et al., 1994; Minghetti and Levi, 1998; Perry, 1998). In addition, microglia up-regulate cell surface molecules including major histocompatibility markers (MHC class I and II) F4/80, complement receptor 3 (CD11b/CD18, OX42) and Griffonia simplicifolia isolectin B4 (Gordon et al., 1988; Perry, 1998; Langmann, 2007a; Lynch, 2009). These markers are classical microglia markers used to detect microglia by immunohistochemistry and immunofluorescence-staining procedures (Kreutzberg, 1996; Streit et al., 1999). The magnitude of microglial activation is influenced by the type and duration of the stimulus, the current CNS microenvironment and exposure to prior and existing stimuli (Schwartz et al., 2006; Perry et al., 2007; Ransohoff and Perry, 2009).

The type of stimulus which activates microglia is very important. In response to certain cytokines such as interferon- $\gamma$  (IFN $\gamma$ ) and tumor necrosis factor-R (TNFR) or after recognition of pathogen-associated molecular patterns (PAMPs), microglia enter a 'classically' activated state normally

associated with strong immune defense (Laskin, 2009). In contrast, interleukin-10 (IL-10) or transforming growth factor- $\beta$  (TGF $\beta$ ) trigger 'alternatively' activated microglia which is associated with resolution of inflammation through phagocytosis of apoptotic neutrophils, reduced production of pro-inflammatory cytokines, and increased expression of mediators important in tissue remodeling, angiogenesis, and wound repair (Duffield, 2003; Van Ginderachter et al., 2006).

Microglia activation occurs very early in response to injury, often preceding reactions of any other cell type (Gehrmann et al., 1995). Time-lapse *in vivo* imaging have shown that microglia appear minutes following injury, polarizing their processes toward the site of injury (Nimmerjahn et al., 2005). Based on these studies as well as many others, microglial response to injury is generally thought to constitute the initial step of a generalized inflammatory response. Once the cause of stimulation has been removed, signals from neurons as well as the microenvironment will efficiently regulate neuroimmune response allowing the tissue to return to homeostatic state. This is in part regulated by the balance of 'classically' and 'alternatively' activated microglia. However, these neuromodulatory mechanisms may become deficient and/or dysregulated under excessive or prolonged inflammatory stimulation induced by disease and injury. In such cases, the microglial function which was initially important for host defense and neuroprotection, can have detrimental and neurotoxic effects (Block et al., 2007). It is now recognized that overly active microglia, normally of the 'classically' active class, are associated with the pathogenesis of several neurodegenerative disorders including Alzheimer's disease, amyotrophic lateral sclerosis (ALS), Parkinson's disease and several retinal degenerative diseases (Boillee et al., 2006; Kim and Joh, 2006; El Khoury et al., 2007).

## 1.4 Inherited Diseases of the Eye

Inherited retinal dystrophies are a heterogeneous group of disorders where an underlying inherited gene defect leads to impaired retinal function. They can be classified according to mode of inheritance, site of retinal dysfunction, age of onset, associated systemic syndromes or the underlying gene defect (Sundaram et al., 2012). To date, the Retnet (Retinal Information Network) database lists 232 genes which lead to retinal disease (<https://sph.uth.edu/retnet/home.htm>). Age-related Macular Degeneration (AMD), is the leading cause of vision loss in industrialized countries and is caused by genetic predisposition as well as environmental factors. Achromatopsia and Retinitis Pigmentosa (RP) together define a large class of monogenic diseases that affect vision

in humans, caused by a wide variety of mutations that disrupt visual transduction and photoreceptor maintenance. Due to the high oxygen consumption that is required for retinal light absorption, photoreceptors in particular, are greatly susceptible to injury and perturbations often resulting in cell death. In most cases, loss of vision is usually caused by photoreceptor loss which occurs through apoptotic mechanisms and/or non-apoptotic mediated cell death (Portera-Cailliau et al., 1994; Sancho-Pelluz et al., 2008).

In the mouse model of X-linked juvenile retinoschisis, Retinoschisis-deficient (*Rs1h-/Y*) mice develop massive photoreceptor degeneration very early in postnatal development, accompanied by splitting or schisis of retinal layers (Weber et al., 2002; Ebert et al., 2009). The *rd1* (retinal degeneration) mouse model, which is a relevant RP model, has early rod photoreceptor degeneration starting at postnatal day 10 which has been attributed to apoptotic mechanisms (Chang et al., 1993) as well oxidative stress (Sanz et al., 2007). Photoreceptor cell death due to apoptosis and oxidative stress has also been reported in AMD animal models as well as patients (Curcio et al., 1996; Winkler et al., 1999; Dunaief et al., 2002). However, recent studies in AMD, *Rs1h-/Y* and *rd1* mouse models now show significant induction of inflammatory markers as well as activation of microglial and Müller cells, which also play a major role in retinal disease progression and degeneration (Gupta et al., 2003; Patel and Chan, 2008; Ding et al., 2009; Ebert et al., 2009).

### **1.4.1 Microglia in Retinal Degeneration**

Microglia activation has also been shown to contribute to retinal degeneration in a number of studies (Langmann, 2007). Both genetic or retinal dystrophies caused by external factors usually harbor active phagocytic microglia at lesion sites/site of cell loss. Numerous studies have shown that microglial activation is not simply a side-effect of hereditary photoreceptor dystrophies, but an active contributor to retinal degeneration (Thanos, 1991; Schuetz and Thanos, 2004; Zeiss and Johnson, 2004; Karlstetter et al., 2010).

Studies done on the aforementioned retinoschisis, *Rs1h-/Y*, mice using DNA-microarray analyses, identified several transcripts from activated microglia cells preceding gene expression patterns related to apoptosis (Gehrig et al., 2007). Furthermore, microglial transformation from ramified to an amoeboid phagocytic morphology coincided with cell death (Ebert et al., 2009). This suggests early microglial activation as a key event preceding/triggering photoreceptor death (Gehrig et al.,

2007; Langmann, 2007). Increased expression of the microglia-activating chemokines MCP-1, MCP-3, as well as high levels of microglia-secreted TNF $\alpha$  were also observed in the retina of *Rd* mice. These observations coincided with prominent microglial migration into the ONL well before photoreceptor apoptosis (Zeiss et al., 2004; Zeng et al., 2005). Diseased retinas from human AMD and RP patients have also revealed the presence of activated microglia in the ONL, bearing phagocytised fragments from dead photoreceptors (Gupta et al., 2003). Studies done by Joly et al. could show both resident and bone-derived macrophages co-operating to remove apoptotic photoreceptors in blue-light injured mouse retinas, indicating recruitment of peripheral macrophages (Joly et al., 2009). In the retinal microenvironment, recruited macrophages transform phenotypically into microglia-like cells and actively contribute to the inflammatory processes (Kaneko et al., 2008). These studies, among many others, imply early microglial activation as an active cause or additive effect of retinal degeneration. However, the molecular mechanism of microglial activation and whether the functional consequences are destined to be detrimental or protective is unclear. It is important to note, that morphology does not accurately reflect the activation state of microglia. As mentioned above, different patterns of activation lead to distinct functional profiles, which may be associated with the common 'activated' morphology (Schwartz et al., 2006). Nonetheless, in most diseases, there is a greater presence of neurotoxic microglia compared to the neuroprotective counterpart.

### 1.4.2 Müller Cells in Retinal Degeneration

Like microglia cells, Müller cells can also become 'activated' or 'reactive' in response to pathological alterations in the retina. This reaction, also known as Müller cell gliosis, is one part of a complex retinal response to pathogens which also includes inflammatory and immune responses. Reactive gliosis may be a cellular attempt to protect retinal tissue from further damage and promote tissue repair by releasing neurotropic factors and antioxidants (Schutte and Werner, 1998). However, some factors which are released by Müller cells, such as vascular endothelial growth factor (VEGF), may at first have neuroprotective effects but later contribute to disease progression by inducing vascular leakage and neovascularization (Miller et al., 1994; Yasuhara et al., 2004). Notably, Müller cells up-regulate glial intermediate filaments vimentin and glial fibrillary acidic protein (GFAP). These are sensitive and non-specific responses to retinal disease and/or injury, which are used as early indicators of retinal stress (Bignami and Dahl, 1979; Lewis and Fisher, 2003). These intermediates are also expressed by some astrocytes when pathogens or

insults occur in the brain. Along with GFAP and vimentin, inflammatory factors such as monocyte chemoattractant protein-1 are also up-regulated and can recruit microglia to site of injury (Nakazawa et al., 2006; Nakazawa et al., 2007b). Microglia, in turn, release oxygen free radicals and cytokines which contribute to photoreceptor apoptosis. A study using GFAP- and vimentin-deficient mice with induced retinal detachment showed reduced microglial infiltration and decreased photoreceptor apoptosis (Nakazawa et al., 2007a). Similar results were also found after experimental blue-light retinal injury in GFAP- and vimentin- deficient rats (Iandiev et al., 2008). In severe cases of gliosis, proliferation of Müller cells contributes to neuronal cell death by impairing tissue homeostasis, which in turn increases the susceptibility of neurons to stressful stimuli in diseased retinas (Fisher et al., 1991).

## **1.5 Neuronal Ceroid Lipofuscinosis (NCL)**

One particular disease which is an inherited degeneration of the retina and CNS is Neuronal Ceroid Lipofuscinosis (NCL), First identified in 1826 by Dr. Otto Christian Stengel, NCL is defined as a progressive degenerative disease of the brain and most cases, retina, in association with intracellular accumulation of storage material known as ceroid lipofuscin. Despite over 100 years of research and the vast accumulation of knowledge on genes, proteins and pathways, there is no treatment for NCL (Haltia, 2003, 2006; Haltia and Goebel, 2012).

### **1.5.1 Characteristics of NCL**

Collectively, the NCLs are the most common cause of progressive encephalopathies in children (Haltia, 2006; Kollmann et al., 2013). Incidence is estimated to be 1:25 000-50 000 in the USA (according to The National Institute of Neurological Disorders and Stroke) and ranging between 1:25 000 and 1:200 000 in European countries (e.g. Norway, Germany and Italy)(Williams, 2011). Up to date, almost 400 causative mutations have been reported in 13 CLN genes (Table 1) (NCL Mutation and Patient Database, <http://www.ucl.ac.uk/ncl/mutation.shtml>). Symptoms of NCL disease include epileptic seizures, ataxia, mental and motor regression, myoclonus and/or visual failure (Warrier et al., 2013). Although there are various kinds of NCL, they do share some common traits: 1) the accumulation of auto-fluorescent, electrondense granules in most nerve cells and, to a lesser extent, in many other cell types, 2) varying degrees of cerebral/cerebellar neurodegeneration (Haltia and Grobel, 2012). It is now becoming evident that severe up regulation

inflammatory processes, microglia and astrocytes are also part of the NCL pathogenesis. Although the relative timing and rate of disease progression differs between different forms of NCL, all end inevitably with the premature death of the affected individual.

The NCLs are subdivided into categories based on molecular genetic findings, age of onset and the ultra structure appearance of storage material (Table 1). The NCLs are normally classified as congenital, infantile, late-infantile, juvenile and adult form (Haltia and Goebel, 2012). NCL diagnosis is based on genetic or enzymatic tests from a blood, skin biopsy or saliva samples. Prerequisite for NCL diagnosis is the existence of intracellular storage material, which can be studied using electron microscopy on lymphocytes from skin/rectal biopsies. Monitoring electroencephalogram (EEG), electroretinogram (ERG), measuring the visual and/or somatosensory evoked potentials (VEPs, SEPs) or performing neuroradiological analyses may also assist the diagnosis of certain forms of NCL (Kousi et al., 2012).

### **1.5.2 NCL as a Lysosomal Storage Disorder**

The NCLs are considered as inherited lysosomal storage disorders (LSDs). Lysosomes are primarily characterized as acidic organelles which contain the primary hydrolysis machinery of the cell required for the degradation of proteins, lipids, and carbohydrates, and whole organelles. Lysosomes are globular or tubular-shaped vacuoles with variable electron-dense constituents. Their lumen is acidic (pH 4.5 – 5) and contains membrane sheets and intraluminal vesicles. LSDs are mostly recessively inherited, fatal diseases characterized by a progressive accumulation of undegraded metabolite(s) in the lysosome but also in other intracellular and extracellular locations. Several types of macromolecules have been identified to be stored in LSDs, including sphingolipids, mucopolysaccharides, oligosaccharides, glycoproteins, lipids, sulfatides, and specific proteins and amino acids (Futerman and van Meer, 2004; Ballabio and Gieselmann, 2009). Most of the LSDs are due to mutations in soluble lysosomal hydrolases but can be caused by a multitude of mutations which cause functional impairment (Ruivo et al., 2009).

Most of the NCL proteins are, in fact, present in the lysosomes where ceroid lipopigments accumulate. Lipofuscin and ceroid are fluorescent storage material largely composed of protein, which in most NCLs is the subunit c of mitochondrial F1-F0-ATP synthase. In certain subtypes, mainly in infantile and congenital disease, the main protein components of the storage material are

sphingolipid activator proteins (saposins) A and D. However, the role NCL proteins play in lysosomes or else-where in the cells as well as NCL disease mechanism is largely unknown (Haltia, 2003; Seehafer and Pearce, 2006).

Table 1: The neuronal ceroid lipofuscinosis classified according to clinical onset, affected gene, protein function, protein location, storage component and first identification of causative gene

Disease	Onset	Gene Affected	Function	Location	Storage component	First identification
<b>CLN1</b>	Infancy	Palmitoyl protein thioesterase 1 (PPT1)	Palmitoyl-thioesterase	Lysosome	Saposin A/D	(Vesa et al., 1995)
<b>CLN2</b>	Late-infancy	Tripeptidyl peptidase 1 (TPP1)	Serine protease	Lysosome	subunit c	(Sleat et al., 1997)
<b>CLN3</b>	Juvenile	CLN3	Unknown	Lysosome Endosome	subunit c	(Consortium, 1995)
<b>CLN4</b>	Adulthood	Cysteine-string protein alpha (CSP $\alpha$ ), DNAJC5	Chaperone	Plasma Membrane	Saposin A/D	(Noskova et al., 2011)
<b>CLN5</b>	Late-infancy	CLN5	Unknown	Lysosome	subunit c	(Savukoski et al., 1998)
<b>CLN6</b>	Late-infancy	CLN6	Unknown	ER	subunit c	(Wheeler et al., 2002)
<b>CLN7</b>	Late-infancy	MFSD8	Unknown	Lysosome	n.d.	(Siintola et al., 2007)
<b>CLN8</b>	Late-infancy	CLN8	Unknown	ER-Golgi intermediate compartment	subunit c	(Ranta et al., 1999)
<b>CLN 10</b>	Congenital	Cathepsin D (CTSD)	Aspartyl endopeptidase	Lysosome	subunit c	(Siintola et al., 2006; Steinfeld et al., 2006)
<b>CLN 11</b>	Adult	Progranulin GRN	Unknown	Extracellular	Saposin D	(Smith et al., 2012)
<b>CLN 12</b>	Juvenile	ATP13A2	Unknown	Lysosome	n.d.	(Bras et al., 2012)
<b>CLN 13</b>	Adult	Cathepsin F (CTSF)	Cysteine protease	Lysosome	n.d.	(Smith et al., 2013)
<b>CLN14</b>	Infantile	Potassium channel tetramerization domain-containing protein 7 (KCTD7)	Unknown	Cytosolic	n.d.	(Staropoli et al., 2012)

**Table 1: List of CLN genes which carry NCL causing mutations.** Abbreviations. CLN1 ect: Ceroid lipofuscinosis 1 ect.; n.d.: not described. References: Kollmann et al., 2013, Warrier et al., 2013, NCL Mutation and Patient Database, <http://www.ucl.ac.uk/ncl/mutation.shtml>

### 1.5.3 Characteristics of CLN3 Mutations

Mutations in the CLN3 gene result in juvenile neuronal ceroid lipofuscinosis (JNCL, Batten disease, OMIM#204200). World wide, JNCL represents the most common form of NCL. Currently, 57

mutations have been characterized in the CLN3 gene (NCL Mutation and Patient Database). The most common mutation is a 1.02 kb deletion of exon 7 and 8 which results in a severely truncated protein with residual function, (Kitzmuller et al., 2008). JNCL usually begins with visual failure due to retinal degeneration at 5–10 years of age. Mental retardation develops slowly and is followed by epilepsy and deterioration of motor skills. Juvenile NCL is also connected to different psychiatric symptoms like aggressiveness, depression and sleep problems. The clinical course is largely variable and the death occurs between 20-30 years of age. At autopsy, the cerebral cortex is narrowed and the weight of the brain is decreased (Haltia, 2003). Unfortunately, because neurological symptoms often begin years after occurrence of visual problems, JNCL patients are considered as otherwise normal children with vision loss often mistaken as a maculopathies (Collins et al., 2006). This significantly delays accurate patient diagnosis.

The CLN3 gene is located on chromosome 16p12 and encodes a hydrophobic transmembrane protein of 438 amino acids called battenin. CLN3 is normally detected in endosomal/lysosomal structures in neurons and gets transported to synaptosomes (Kyttala et al., 2004). CLN3 functions are postulated to include lysosomal acidification, membrane fusion, vesicular transport, autophagy and proteolipid modification (Jalanko and Braulke, 2009; Kollmann et al., 2013). However, the precise function of CLN3 remains elusive, making it difficult to evaluate the impact of the mutations on the resultant peptides (Kollmann et al., 2013).

#### **1.5.4 Characteristics of CLN6 Mutations**

Mutations in the CLN6 gene cause a variant late infantile NCL (vLINCL; OMIM#601780) (Gao et al., 2002; Wheeler et al., 2002), as well as an adult form termed Kufs type A disease (OMIM#204300) (Arsov et al., 2011). At present, 68 disease-causing mutations have been described (NCL Mutation and Patient Database). The most common mutation, which leads to vLINCL, is a 1-bp insertion in exon 4 (c.316insC) causing a frame shift mutation and premature stop codon resulting in a truncated protein (Kurze et al., 2010). The age of onset for vLINCL caused by CLN6 mutations is between 18 months and 8 years of age with the most common presenting features being motor delay, dysarthria and ataxia. Additional symptoms include mental regression, speech impairments and in approximately 50 percent of cases seizures and loss of vision (Mole et al., 2005; Moore et al., 2008). Disease progression is rather variable with death occurring between 5 to 30 years of age (Pena et al., 2001; Jalanko and Braulke, 2009).

The CLN6 gene on chromosome 15q23 encodes an endoplasmatic reticulum (ER) resident transmembrane protein 331 amino acids long, named linclin or CLN6p. CLN6 is conserved across vertebrates showing no sequence homology with other proteins. Mutations in CLN6 do not have an impact on normal distribution or its ability to dimerize (Mole et al., 2004; Kurze et al., 2010). Instead, it is postulated that mutations exert their pathogenic effect on the stability and function of mutant polypeptides, possibly reducing rate of synthesis and stability compared to wild type peptides (Kurze et al., 2010). CLN6p has also been shown to interact with collapsin response mediator protein-2 (CRMP-2) which controls axon growth (Benedict et al., 2009). Recent studies have now shown the CLN6<sup>nclf</sup> mutation also results in disruption of the autophagy-lysosome degradation pathway suggesting the CLN6 protein may be important for fusing autophagosomes and lysosomes (Thelen et al., 2012).

### 1.5.5 Animal Models of CLN3 and CLN6

Animal models exist for all subtypes of NCL disorders (NCL Animal Models Database <http://www.ucl.ac.uk/ncl/animal.shtml>). These are either spontaneously occurring or engineered and they have been described in organisms ranging from the single celled yeast to larger animal models such as sheep and dog (Cooper et al., 2006).

Orthologs of CLN3 can be found across many species and have been studied in *Drosophila Melanogaster*, *C. elegans*, unicellular yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* and mouse models. Pioneering work done on CLN3-deficiency yeast models, *btn1*, significantly contributed to understanding CLN3 function (Pearce and Sherman, 1997; Gachet et al., 2005; Rakheja et al., 2008). In order to better understand CLN3 mutations in mammals, four mouse models of JNCL have been established and characterized to varying degrees (Cooper, 2006). All mouse models display recessive features of JNCL including accumulation of ceroid lipofuscin, brain gliosis, neurological dysfunction and neurodegeneration. The *Cln3*<sup>Δex7/8</sup> knock-in mouse represents the only genetically accurate JNCL mouse model, and therefore may be most predictive of the earliest molecular and cellular consequences of CLN3 mutation in JNCL (Cotman et al., 2002) and the only one which has been fully phenotyped (Strapoli et al., 2012).

In contrast to the engineered CLN3 models, CLN6 disease occurs naturally in mouse, sheep and dog (Jolly et al., 1989; Gao et al., 2002; Wheeler et al., 2002; Tammen et al., 2006; Katz et al., 2011). The

CLN6 mutant mouse model, *Cln6<sup>ncf</sup>*, possesses an identical mutation (c.307insC) to the most common CLN6 human mutation mentioned. The course of the *Cln6<sup>ncf</sup>* neurodegenerative phenotype also recapitulates the human CLN6 disease with homozygous mice developing progressive retinal atrophy, cerebral atrophy, spastic limb paresis starting at eight months, paralysis and premature death at one year of age (Bronson et al., 1998; Wheeler et al., 2002; Sharp et al., 2003; Siintola et al., 2005).

### 1.5.6 Retinal Degeneration in NCL

Vision loss is typically evident in patients with NCL at early age making ophthalmologists often the first specialists seen by patients (Birch, 1999). Retinas of NCL patients are normally affected by two different pathological processes, 1- accumulation of disease specific lipopigments in the neuronal perikarya and retinal pigment epithelium cells, 2- progressive degeneration of the neuronal elements, commencing at the photoreceptors. At autopsy, patients eyes normally exhibit severe atrophy of the entire retina (Goebel, 1992).

Many NCL models also exhibit varying levels of retinal degeneration and vision problems. Among them are mutant forms of CLN1, CLN3, CLN5, CLN6, CLN8 and CLN10, which have been studied using electroretinograms (ERGs). ERGs are a good method for measuring retinal cell function and can be used on both patients and animals. Briefly, ERGs measure electrical responses from the retina upon light stimulation which are recorded as waves; the a-wave which is the first negative component, indicating the general health of the photoreceptors, followed by the b-wave which is has a large positive amplitude, reflecting the health of the inner layers of the retina (Creel, 2013).

Retinal studies in the *Cln8<sup>mnd</sup>* mouse showed reduced ERG amplitudes in both the a- and b-wave starting at two months until the signals became barely recordable by five months of age. These functional measurements were accompanied by obvious morphological retinal degeneration which appeared four months before motor paralysis starts (Chang et al., 2002). ERG studies done on *Cln3<sup>Δex7-8</sup>* mice past nine months of age showed a reduction in the b-wave whilst maintaining a relatively normal a-wave function, indicating that the inner retina is the most affected region (Strapoli et al., 2011). *Ppt1<sup>-/-</sup>* (CLN1) mice, a model for the infantile form of human NCL, showed only moderate changes in retinal morphology and reduction in the b-wave amplitudes (Lei et al., 2006). Retinal degeneration in *Cln6<sup>ncf</sup>* mice have also been studied, showing retinal degeneration

starting at four months of age resulting in loss of the ONL by nine months of age (Bronson et al., 1998).

### 1.5.7 Glial Activation in NCL

Neuropathology, genome wide expression profiling and cellular analyses in several NCL mouse models have firmly established hyperactivity of the immune system prior to neurodegenerative events as a potential early disease mechanism (Elshatory et al., 2003; Chattopadhyay et al., 2004; Kopra et al., 2004; Jalanko et al., 2005; Jalanko et al., 2006). Autopsy material from patients with different forms of NCL also show consistent and regionally specific pattern of astrogliosis and microglial activation in the brain (Tyynela et al., 2004).

Early prominent activation of astrocytes and microglia were first observed in CLN6-deficient South Hampshire sheep (Oswald et al., 2005). Activated astrocytes appeared in developing white matter 40–20 days before birth and astrocytic activation within the gray matter 20 days before birth. Clusters of activated microglia were detected in upper cortical gray matter layers 12 days after birth defining regions most vulnerable to neurodegeneration, which starts at two months of age (Oswald et al., 2005). *Cln6<sup>ncif</sup>* mouse brains also show localized reactive astrocytes and microglia, most prominent in the thalamocortical system, starting between five to six months of age (Bronson et al., 1998; Thelen et al., 2012).

Increased reactive astrocytes is the first histopathological change observed in specific regions of the *Ppt1*<sup>-/-</sup> mouse brain, starting at 3 months of age. These regions also suffer significant neuronal loss subsequent to gliosis (Kielar et al., 2007; Macauley et al., 2009). However, when these mice were crossed with *GFAP*<sup>-/-</sup> *Vimentin*<sup>-/-</sup> mice, resulting in loss of astrocytes in the brain, it resulted in an accelerated brain degeneration (Macauley et al., 2011). These experiments highlight the protective and deleterious effects gliosis can have. Moreover, studies done by Groh et al., in which lymphocytes were inactivated in *Ppt1*<sup>-/-</sup> mice, showed a substantial disease attenuation, unequivocally defining immune cells as pathogenic mediators in infantile NCL (Groh et al., 2013).

Studies done on *Cln3*<sup>-/-</sup> and *Cln3*<sup>*Δex7-8*</sup> mice also showed selective loss of inhibitory interneurons and early low level glial activation preceding neuron loss most pronounced in the thalamocortical system (Pontikis et al., 2004; Pontikis et al., 2005).

## 1.6 Glial Attenuation with Natural Compounds

The presence of glial activation in numerous degenerative diseases has resulted in the search for therapeutic interventions which can modulate astrocyte and microglia activity while reducing inflammatory marker expression and simultaneously support neuronal survival. Therapeutic strategies include targeting ligands which activate microglia (Jin et al., 2007; Veiga et al., 2007), enhancing protective endogenous mechanisms (Zhu et al., 1999) and immuno-modulation with natural compounds (Ebert et al., 2009; Dirscherl et al., 2010; Karlstetter et al., 2011).

### 1.6.1 Curcumin

Curcumin ((E,E)-1,7-bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione), derived from the plant *Curcuma longa*, is a major constituent of tumeric which has been used as herbal medicine in India and China for centuries (Ammon and Wahl, 1991). Curcumin has been shown to inhibit the defense program of microglia by diminishing the production of nitric oxide and secretion of pro-inflammatory cytokines (Jung et al., 2006; Jin et al., 2007). It has also been shown to protect dopaminergic neurons against microglia-mediated neurotoxicity (He et al., 2010). Curcumin supplementation in a rat model of acute-light damage had functional and structural protection of photoreceptors along with decreased inflammatory gene expression (Mandal et al., 2009). Curcumin treated activated microglia become neuroprotective and can rescue neurons from apoptosis *in vitro* (Yang et al., 2008) as well as reduce microglial migration (Karlstetter et al., 2011).

### 1.6.2 Luteolin

Luteolin (3',4',5,7-tetrahydroxyflavone) is a flavonoid abundant in parsley, green pepper, celery, and chamomile tea (Lopez-Lazaro, 2009). It has been shown to suppress pro-inflammatory cytokine IL-6 production in macrophages by blocking nuclear factor kappa B (NFkB) and activator protein 1 signaling pathways (Chen et al., 2007). Like curcumin, it has also been shown to inhibit production of nitric oxide (Hu and Kitts, 2004). Supplementation studies done on aged mice between 22-24 months of age showed reduced microglia activity in the hippocampus as well as reduced inflammatory marker expression (Jang et al., 2010). Luteolin treatment also attenuates microglial activation and induces a neuroprotective phenotype *in vitro* (Chen et al., 2008; Dirscherl et al., 2010).

### 1.6.3 DHA

Docosahexaenoic acid (DHA, 22:6n-3), a polyunsaturated fatty acid enriched in fish oil also dampens microglial nitric oxide production (Antonietta Ajmone-Cat et al., 2012) and attenuates microglial reactivity in a mouse model of inherited retinal degeneration (Ebert et al., 2009). DHA is highly enriched in the retina and is a precursor for neuroprotectin D1, promoting the survival of photoreceptors and RPE cells (Mukherjee et al., 2007). DHA has also been shown to inhibit the synthesis of inflammatory products by microglia allowing better survival of neural progenitor cells (Antonietta Ajmone-Cat et al., 2012). Furthermore, it has been previously reported that patients with juvenile NCL have reduced DHA levels in plasma and cerebral cortex, which may contribute to retinal and brain degeneration (Kohlschutter et al., 1993b).

## 1.7 Aim of the Thesis

Despite all the studies done on glial activation in the NCL brain, the presence of glial activation in the retina and whether it is the cause of retinal degeneration has not been studied. It is postulated that retinal glial activation in CLN mouse models represents an early event before the onset of overt neurodegenerative symptoms which leads to retinal dystrophy and blindness. Furthermore, therapeutic targeting of retinal glia cells and inflammatory processes could delay neuronal degeneration, hence improving symptoms. Results from immuno-modulation of the retina could be a basis to further evaluate the potential of immune-related therapies in the brain.

The aim of this study was divided into three parts.

1. Characterize the visual function and retinal degeneration of two NCL mouse models, *Cln3<sup>Δex7-8</sup>* and *Cln6<sup>nclf</sup>*, using optokinetic and electroretinogram measurements, as well as histological assessment.
2. Analysis retinal microglia and Müller cell activation in relation to progressive neurodegeneration using immunohistochemistry as well as glial and inflammatory marker gene expression.
3. Select one mouse line with the most prominent glial activation, which best correlates to onset of retinal degeneration, and do supplementation studies with curcumin, luteolin and

DHA in order to attenuate inflammatory processes resulting in reduced retinal degeneration.

## 2. Materials

All materials, software and machines used in this thesis were provided by the Institute of Human Genetics at the University Clinic Regensburg, unless otherwise specified.

### 2.1 Mouse Models

Table 2: Mouse models used in thesis studies

Mouse Model	Origin	Mutation	Genetic Background	Reference
<i>Cln3</i> <sup>Δex7-8</sup>	Charité Berlin, Dr. Klaus Ruther	Knock-In	C57BL/6N	Cotmann et al., 2002

## 3 Methods

### 3.1 Mouse Lines and Husbandry

The animals used in this study were housed in an air-conditioned environment at 20°C – 22°C and were subject to a constant 12 hours light-dark cycle with free access to water and standard mouse diet. Light intensity during light phase was 15 lux. Animal health status was regularly controlled and all experimental protocols were approved by the Committee of Animal Health and Care of the local government and conformed to international guidelines on the ethical use of animals. All efforts were made to minimize the number of animals used and their suffering. The required animals were killed, depending on their age, by either direct decapitation or by CO<sub>2</sub> asphyxiation with subsequent cervical dislocation. Mice were either genotyped using PCR or sequencing.

### 3.2 Mouse Genotyping

#### 3.2.1 DNA Extractions

Mouse tail tips were cut using a sharp blade and the DNA extracted by incubating tails for 20 min in 75µl Alkaline Extraction Solution at 95°C, chilling samples on ice and then adding 75µl Neutralizing solution.

#### 3.2.2 Photometric determination of DNA concentration

A spectrophotometer (Nanodrop ND-1000) was used to determine the concentration and purity of the DNA samples. Absorbance was measured at 260 nm and 280 nm and was calculated using the Lambert-Beer law:  $E = \epsilon \cdot d \cdot c$ ; with E being the extinction,  $\epsilon$  the molar extinction coefficient, d the thickness of the sample and c the concentration of the sample. An extinction factor of 1 represents 50 µg/ml of double-stranded DNA. DNA was considered pure between A<sub>260/280</sub> of 1.8 to 2.2 using nuclease-free water as a reference.

#### 3.2.3. DNA amplification with PCR

Polymerase chain reaction (PCR) is the standard methods used for amplifying small quantities of template DNA within a short time. DNA is mixed with forward and reverse primers, taq-

polymerase, deoxynucleotide triphosphates (dNTPs) and buffer. During the first step, template DNA is denatured at 95°C. Here, the sense and antisense strand are separated from each other. During the annealing-phase, primers bind to the single stranded DNA. The annealing temperature is dependent on every single pair of oligonucleotide (primer-pair). In the last step, taq-polymerase elongates the primers according to the template DNA. The temperature used in the elongation-phase (72°C) is optimal for the hyperthermophil bacteria *Thermus aquaticus* activity, from which the taq-polymerase enzyme is isolated. CLN3 DNA were amplified using primer pairs (Table 16 ), PCR cocktail mix (Table 15) and PCR program (Table 17).

Mouse line	Composition	1x dilution (µl)	c (Stocks)	c (Dilution)
<b>CLN3</b>	dNTP-mix	4.00	1.25mM	0.2mM
	Primer Forward	0.625	10µM	0.25µM
	Primer Reverse	0.625	10µM	0.25µM
	15x Buffer (25mM MgCl <sub>2</sub> )	2.5	25mM	2mM
	House Taq polymerase	0.625	2U/µl	0.05U/µl
	Nuclease-free water	14.625

### 3.2.4 DNA amplification for Sequencing

DNA from CLN6<sup>ncf</sup> mice was sequenced for an additional cystein insertiona in a six cystein sequence found the normal CLN6 amino acid sequence (Table 16, 18). This method first requires the amplification of total DNA using a Qiagen Taq Core kit, followed by digestion of DNA to separate the strands, then amplification of one of the strands using one of the primer pairs and a

fluorescent dye. Once the dye is incorporated into the elongating strand, it causes the polymerase to fall off, resulting in different lengths of DNA. Extensive washing steps are done to ensure all the unused dye is removed leaving behind pure DNA. DNA is then diluted in formamide, placed in a 96-well plate and sequenced using the automated capillary electrophoresis 3130xl Genetic Analyzer from ABI. Heated formamide causes DNA to denature allowing DNA strands to separate by size and migrate down the capillary at different speeds. The analyzer then uses a laser to excite the fluorescent material found at the end of the strand causing the DNA to be colored. The computer is then able to read the colors and determine the order of the bases in the sample. The Genetic Analyzer is operated by the Diagnostic Department at the Institute of Human Genetics at the University Clinic Regensburg.

Step	Solution composition	PCR	PCR temperature (°C), time	PCR cycle

Table 18. Method for DNA sequencing

### 3.2.5 DNA Separation and Analysis

Quantitative and qualitative DNA analysis were done via agarose gel electrophoresis. Agarose gel electrophoresis is a standard method to separate DNA fragments according to their molecular weight. The phosphate backbone of nucleic acids is ionized, thus deoxynucleotides are present as

anions and migrate from the cathode to the anode in an electric field. Depending on the size of the fragments, 1.5 % (w/v) or 2 % (w/v), agarose gel was prepared by dissolving agarose in an appropriate amount of TBE buffer and adding a few drops of ethidium bromide. The solution was transferred into a gel casting tray and a removable comb was added. DNA samples were mixed with 10x DNA loading buffer and 1x TBE buffer. After polymerization the comb was removed and the samples were loaded. For size determination, a 1 kb DNA ladder was used. Separation occurred at 120 to 150V and took 30 to 45 minutes. ethidium bromide is a DNA intercalating agent allowing DNA fragments to be visualized using UV irradiation (dark hood). The agarose gel was documented using the Argus 3.0 software.

### **3.2.6 Sequence Analysis**

Sequences obtained from the Genetic Analyzer were viewed using Sequence Scanner 1.0 and compared to a reference sequence using Tools ClustalW2 software.

## **3.3 Retinal Preparations for Experiments**

### **3.3.1 Cryo-embedding and Sections**

Enucleated eyes were embedded in TissueTek O.C.T Compound after a short washing step in 1x PBS, flash-frozen with dry ice and stored at - 80°C. For permanent fixation of the tissue, the eyes were fixed in 4 % PFA for 2 hours and incubated in 18 % sucrose overnight followed by TissueTek embedding. 10 µm cryosections were prepared with a CryoMicrotome and mounted onto a Polysin-slide. Cryosections were stored at - 80°C for further experiments.

### **3.3.2 Whole Retinal Flat Mounts**

Eyes were enucleated and fixed in 4 % PFA (4 h/4°C). Using a standard light microscope, a hole was made in the cornea and the lens removed. The retina was carefully separated from the RPE and stored in 1x PBS for further experiments.

### 3.3.3 Morphometry Experiments

Before enucleation, eyes were branded on the superiour limbus. Eyes were fixed for 24h in Ito's fixative (Karnovsky, 1965) and embedded in Epon. Sections 1  $\mu$ m in thickness were cut along the nasal-temporal plane and stained with fuchsin/methylene blue. Branded enucleated eyes were further handled by Prof. Dr. Ernst Tamm's laboratory until eyes were sectioned and ready for analysis.

## 3.4 Morphological and Immunohistological Analyses of Prepared Retinae

### 3.4.1 Hematoxylin and Eosin Stain

Hematoxylin and eosin (HE) stain allows for a quick overview of the tissue morphology. This method stains the cell bodies blue and the tissue around the cell bodies with a red-ish color. Non-fixed retinal sections were fixed in 100% ethanol (ETOH) for 20 min at -20°C followed with a 5 min washing step in PBS and hematoxylin stain for 5 min. Hematoxylin was washed out with gentle running water for 15 min, stained with 1% Eosin Y diluted in water for 3 min, washed for 10 sec in water and dehydrated in increasing amount of ETOH (70% 5 sec, 80% 5 sec, 90% 5 sec and 100% 4 min). Samples were then incubated with 100% Xylol for 3 min and embedded with Xylol-soluble Entellan and cover slip.

### 3.4.2 Immunohistochemical Stain of Retinal Sections

Cryosections were thawed and air dried at room temperature (RT). Samples which required Iba1 staining required fixed sections which were first boarded with liquid barrier and further fixed with 4% PFA for 6 min. After fixation, cryosections were washed 3 times with 1x PBS for 5 minutes followed by a 10 min re-hydrating step. Sections were then blocked with BLOTT0 30 min at RT and incubated with primary antibody overnight. Samples were then washed with 1x PBS and incubated with fluorescently labelled secondary antibody for 1 hour at RT, diluted in 1x PBS (dilutions in table 5 and 6 ). During the incubation and all the following steps, the slides were covered to avoid bleaching from light. The nuclei were counterstained with 0.1  $\mu$ g/ml DAPI (10 min/RT). Cryosections were embedded with Dako fluorescent mounting medium.

### 3.4.3 Immunohistochemical Stain of Retinal Flat Mounts

Prepared retinae were incubated with 25% Triton-X/ 25% Tween-20 on a shaker (4°C/ON) to ensure full permeability of the tissue. Tissues were then washed extensively with 1x PBS and followed the same staining procedure as above. Flat mounts were not counter stained with DAPI. Stained flat mounts were cut at four different sections to eliminate the natural rounding of the retina and were then embedded with DAKO fluorescent mounting medium.

### 3.4.4 TUNEL Assay

Cleavage of genomic DNA during apoptosis causes 'nicks' or breaks in the DNA strand(s). These breaks can be visualized by labeling the free 3'-OH end with modified nucleotides in an enzymatic reaction (terminal deoxynucleotidyl transferase dUTP nick end labeling, TUNEL). The first step is to mark the broken strand with deoxynucleotidyl transferase using terminal transferase (TdT), which catalyzes the polymerization of labeled nucleotides to free 3'-OH DNA ends (TUNEL reaction). Coupled to an anti-fluorescein antibody, 3'-OH attached fluorescein, also known as the peroxidase, can be detected. After subsequent substrate reaction, stained cryosections can be analyzed.

Cryosections were fixed in 4% PFA solution (20 min, RT) for 30 min and rehydrated in 1x PBS. Endogenous peroxidase activity was saturated with 3% H<sub>2</sub>O<sub>2</sub> solution (10 min / RT), followed by tissue permeabilization (2 min, 4°C). The cryosections were treated with 50 µl TUNEL reaction mix from the In Situ Cell Death Detection Kit, which was freshly prepared by diluting enzyme solution with label solution 1:10 (37°C, 5% CO<sub>2</sub>, 60 min). As a negative control, label solution without enzyme solution was used. For a positive control, cryosections treated with recombinant DNase I solution (3,000 U/ul) prior to incubation with TUNEL reaction mix was used (10 min / RT). The TUNEL stained DNA fragments were detected using green fluorescence. Nuclei were counter-stained with DAPI and mounted using DAKO mounting media.

### 3.4.5 Microscopy

CLN3 samples and TUNEL stains were viewed using Zeiss Axioskop2 MOT Plus fluorescence microscope at 40x magnification. The appropriate filters were used to look at antibodies (488nm), auto-fluorescence (594nm) and DAPI stain (405nm). This microscope also allowed for bright field

analysis of HE stained tissues. All pictures were processed using Zeiss AxioVision LE 4.5. CLN6<sup>ncf</sup> retinal sections were studied and imaged using Axioimager Z1 Apotome Microscope at 100x magnification. Flat mounts were mounted and view with Axioimager Z2 Apotome Microscope at 100x magnification using z-stacks of inner and outer plexiform layers as indicated by fluorescent sidebars. CLN6<sup>ncf</sup> retinal sections were further processed using AxioVision LE 4.5 whilst flat mounts were processes using Zen 2012.

### 3.4.6 Retinal Morphometry Analysis

Eyes prepared for morphometry experiments were viewed using Axioimager Z1 Apotome Microscope under bright light settings. The entire retina was imaged using 63x magnification and stitched together using the fully licensed AxioVision software. The length of superior and anterior retina were measured using a curved line starting from the optic nerve head (ONH) to the end of the retina. The retinal segment was divided into ten equal parts where cross-length measurements of the whole retina and photoreceptor were measured. All measurements were exported into Microsoft Excel and analyzed.

## 3.5 Behaviour and Retinal Function Studies

### 3.5.1 Optomotry

The virtual optomotor system allows for rapid quantification of mouse visual acuity as previously described (Prusky et al., 2004; Douglas et al., 2005). Freely moving mice were place on a platform in the middle of a virtual cylinder made of four computer monitors projecting moving sine wave gratings of various spatial frequencies. The mice were visualized using a video camera found on the lid of the optomotor system which was connected to computer program OptoMotry. This enable the experimenter to track the behavior of the mice without interference. Mice were placed on the platform one at a time, and acclimated to their environment by keeping the monitors dim and gray. At all times, the mouse's head was tracked using a crosshair cursor superimposed in the video image. The coordinates of the crosshair cursor are used as to center the rotation of cylinder thus maintaining the virtual walls of the cylinder at a constant distance from the animal and effectively maintaining the spatial frequency of the grating. Once the mouse had settled and stopped moving, the gray monitors were replaced with a low-spatial-frequency sine wave grating

projected on the monitors. If the mouse was able to perceive the grating, it would move its head and neck in concert with the rotation. This was repeated a few times with short dim pauses in between to ensure accurate readings. The spatial frequency of the grating was increased until the mouse no longer responded. The software controlled the speed of rotation, geometry of the cylinder, the spatial frequency and contrast of the stimuli and enabled live video feedback of the testing arena. The experiment ended when the software had enough data to correctly assess the visual acuity of the animal. Experiments lasted between 10-30 minutes. If, during the experiment, the mouse fell off the platform, it was simply placed on the platform the experiments continued.

**Figure 3. Schematic representation of the Optomotor machine.** A. Side view. The mouse is placed on the platform and the sine wave grating rotate on the screen surrounding the mouse. B. Top view as seen by video camera. C. The mouse head is the center of the rotation of the cylinder. D. When the cylinder is rotating, the mouse tracks the movement with its head and neck. These images were adapted from Prusky et al., 2004.

### 3.5.1 Rotarod

Rotarod experiments to assess motor or cognitive difficulties were done on two subsequent days on an accelerating Rotarod which accelerated 4-40 rpm in one minute. The speed and time at which the mouse fell off the rotarod was recorded. Rotarod apparatus was cleaned after every experiment. Experiments were performed three times with 15 minute resting time in between.

### 3.5.2 Electroretinograms

All electroretinograms (ERGs) were performed by Prof. Dr. med. Herbert Jägle and Dr. med. Cornelia Volz from the University Eye Clinic in Regensburg. A brief method outline was provided by Prof. Jägle. Mice were dark adapted for at least 12 hours before the experiments and subsequently anesthetized by subcutaneous injection of ketamine and xylazine. Pupils were dilated with tropicamide eyedrops. Silver needle electrodes served as reference (fore-head) and ground (tail) and gold wire ring electrodes as active electrodes. Corneregel was applied to keep the eye hydrated and maintain good electrical contact. ERGs were recorded using a Ganzfeld bowl and an amplifier & recording unit. ERGs were recorded from both eyes simultaneously, band-pass filtered (1 to 300 Hz) and averaged. Single flash scotopic (dark adapted) responses to a series of ten LED-flash intensities ranging from -3.5 to 1.0 log cds/m<sup>2</sup> with an inter stimulus interval of 2 s up to 20 s for the highest intensity were recorded. Response waveforms were analyzed by means of trough and peak amplitude and implicit time measurement. All analysis and plotting was carried out with R 2.14.2 and gplot 0.9.

## 3.6 RNA Gene Expression Analysis

Total RNA was isolated from the retina of wild type and mutant mice. All conditions corresponded to those recommended for the RNeasy Kits from Qiagen. All experiments were carried out in nuclease free environment and samples were always kept on ice. The yield of the RNA isolation depends on the amount of retina removed and the state of the tissue upon removal as well as handling during the experiment.

### 3.6.1 RNA Isolation

RNA isolation from retinal tissue was carried out using the RNeasy Kit from Qiagen. This method allows purification of total RNA on hydrophilic silicone gel columns using the appropriate buffer systems. First, tissues were homogenized in a buffer containing guanidinium isothiocyanate and lysed (RLT buffer). This chaotropic salt denatures all proteins, including RNases and thus preserves the RNA from degradation. Tissues were then homogenized using a tissue lyzer (2 x 30 sec, 30 Hz). 70% ethanol was added to the supernatant of the homogenate, allowing binding to the columns. During subsequent centrifugation (13,000 rpm, 1 min, RT), RNA molecules of 200 nucleotides bound to the silicon based column whilst the rest of the solution was removed. Subsequent washing and centrifugation with RW1 and RPE buffer resulted in pure RNA which was eluted with a corresponding volume of nuclease water by centrifugation (13,000 rpm, 1 min, RT). RNA was kept at -80 °C until further use

### 3.6.2 Photometric determination of RNA concentration

RNA concentrations were measured the same as DNA samples (see above). A wavelength of 280 nm provided an indication of possible contamination of the RNA sample with proteins, a wavelength of 260 nm corresponds to the absorption maximum of the RNA bases. An extinction factor of 1 represents 40 µg/ml RNA. Pure RNA has an absorbance ratio  $A_{260}/A_{280}$  of 2.0. Nuclease-free water was used as reference.

### 3.6.3 Reverse Transcription

Isolated RNA cannot be used as a template in subsequent PCRs, therefore it has to be rewritten (reverse transcription) into a complementary DNA strand (cDNA). First-strand complementary DNA was carried out using the RevertAid™ H Minus First Strand cDNA Synthesis Kit from Fermentas. This includes the RevertAid™ H Minus M-MuLV reverse transcriptase from Moloney murine leukemia virus. This enzyme has an optimum temperature of 42-45°C and can synthesis cDNA up to 13 kb in length.

The reaction takes place as follows:

1. 1-3 µg of RNA are diluted into a total volume of 11 µl of nuclease-free water
2. 1 µl of hexamer primer is added

3. The reaction is incubated at 70°C for 5 min
4. 4 µl of Reaction Buffer + 1 µl of nuclease-free water + 2 µl of 10nM dNTP mix is added
5. The reaction is incubated at 25°C for 5 min
6. 1 µl M-MuLV Reverse Transcriptase (200 U/µl) is added
7. The reaction is incubated at 25°C for 10 min
8. The reaction is incubated at 42°C for 60 min
9. The reaction is incubated at 70°C for 10 min (denaturing of the transcriptase)
10. The reaction is diluted with the appropriate amount of nuclease- free water and store at -20°C until needed.

### 3.6.4 TaqMan technology

TaqMan PCR uses cyclic amplification of specific PCR product along with fluorescently labeled probes (Universal sample Library Probes), which target the desired sequence. The advantages of the TaqMan technology are its high sensitivity (<5 ng template sufficient) and specificity, good reproducibility and accurate quantification of mRNA. Each probe consists of eight or nine nucleotides attached to a fluorophore linked reporter (5' end) and a quencher (3' end) which is complementary to the target sequence. The quencher dye suppresses the fluorescence of the reporter by means of fluorescence resonance energy transfer (FRET). As long as the reporter and the quencher are in proximity, quenching inhibits any fluorescent signals (Fig. 4).

**Figure 4. The principle of TaqMan technology.** The probe (in purple) is attached to the fluorophore linked reporter (R) and fluorophore quencher (Q). The forward primer is in yellow and the reverse primer in red. Image adapted from [http://www.asuragen.com/Services/services/gene\\_expression/ab\\_taqman.aspx](http://www.asuragen.com/Services/services/gene_expression/ab_taqman.aspx)

The probes first anneal to a specific region on single-stranded DNA which is amplified by designated primers. As the taq polymerase extends the primer and synthesizes nascent DNA, the 5' to 3' exonuclease activity of the polymerase cleaves the probe which is annealed to the DNA. This cleavage causes the fluorophore to be released from the reporter which breaks its close proximity to the quencher molecule allowing fluorescence of the fluorophore. With every PCR cycle, the fluorescence intensity increases and is directly dependent on the amount of DNA template present in the PCR (Fig. 6 D). The Universal Library sample uses probes made of locked nucleic acids (LNA). LNAs are modified nucleotides which have increased affinity for hybridization with complementary nucleotides whilst maintaining specificity and melting temperature. The real time RT-PCR reactions were performed on 384-well microtiter plates which were scanned after every cycle with a laser. The fluorescence intensity was calculated by the SDS 2.3 software program connected to the real time PCR system. For the quantification of 50 ng cDNA, a PCR protocol of 40 cycles was used (denaturation 95 ° C, 40 sec, annealing 60 ° C, 60 sec, elongation, 72 ° C, 2 min). The real time RT-PCR analysis was performed in duplicates. PCR solution composition is found in Table 19

Compostion	1x dilution (µl)	[ ]Stocks	[ ]Dilution
<b>2x TaqMan Gene Expression Mastermix</b>	5	2x	1x
<b>Primer (forward)</b>	1	10 µM	1 µM
<b>Primer (reverse)</b>	1	10 µM	1 µM
<b>Universal ProbeLibrary Probe</b>	0.125	10 µM	0.125 µM
<b>Nuclease free water</b>	0.375		
<b>cDNA (0,02 µg/µl)</b>	2.5		

Table 19. 10 µl TaqMan solution

### 3.6.5 Relative Quantification

The raw data from the real time RT-PCR experiments can be analyzed using either absolute or relative quantification. This work only required relative quantification, which will be described in detail. Replication of the cDNA during the PCR reaction increases exponentially. This can be represented in a diagram, plotting the fluorescence measured after each cycle to the number of cycles. As the amount of fluorescence depends directly on the amount of DNA template initially provided, the comparison of gene expression from different samples requires analysis of the CT values of each individual reaction. The CT-value (Cycle Threshold) is a threshold value that is placed in the linear region of the amplification curve where there is a statistically significant increase in gene expression. The CT value is where the threshold line intersects the amplification

curve. Therefore, greater initial DNA template have a lower gene expression where as less DNA template will have more. Relative quantification is based on a calibrator, a wild type sample, which is set to one. In addition, the measured gene expression values are normalized to a reference, or housekeeping, gene. A good housekeeping is characterized by a constant gene expression in the desired tissue. Normalizing a sample to a reference gene within that sample eliminates human experimental error and ensures accurate comparisons of the gene expression with other samples. The housekeeping gene used in all experiments was murine ATPase. CT values and relative quantification with the  $\Delta\Delta CT$  method was done using the RQ Manager 2.1 software:

1. Calculation of average CT value --> CT Avg
2. Normalization to average CT value of reference gene ATPase:  
 $CT\ Avg\ (Gene) - CT\ Avg\ (Atpase)$  -->  $\Delta CT\ Avg$
3. In reference to the calibrator  
 $\Delta CT\ Avg\ (Probe) - \Delta CT\ Avg\ (calibrator)$  -->  $\Delta\Delta CT\ Avg$
4. Relative difference in gene expression -->  $2^{-\Delta\Delta CT\ Avg}$

### 3.7 Food Supplementation Study

Experimental mouse diets were produced at SSNIFF Spezialdiäten GmbH (Soest, Germany) consisting of standard mouse diet EF-M (control) supplemented with either 0.6% Curcumin, 0.6% Luteolin or 5% DHA. Mice received supplement diets as soon as they were weaned (post natal day 21-23) and were fed for 30 weeks. Body weight were measured on a weekly basis for the duration of the study.

### 3.8 Statistics

real time RT-PCR data from different mouse ages were analyzed using a two-way ANOVA with Bonferroni post-test. real time RT-PCR data from the food supplementation study were analyzed with a Kruskal-Wallis ANOVA. Rotarod and ERG experiments were analyzed using a one-way ANOVA with Bonferroni post-test.  $P \leq 0.05$  was considered as statistically significant.

## 4. Results

### 4.1 Characterization of the *Cln3<sup>Δex7-8</sup>* Retina

Previous studies done on *Cln3<sup>Δex7-8</sup>* mice showed localized glial activation and inflammation preceding and during neuronal degeneration in the brain (Pontikis et al., 2004; Pontikis et al., 2005). However, little is known about retinal degeneration in this mouse model and whether reactive glia and inflammation play a role. One of the objectives of this thesis was to characterize the morphological and functional degeneration in the *Cln3<sup>Δex7-8</sup>* retina and determine if Müller cells and microglia, in particular, play an active role in degeneration.

#### 4.1.1 Histological Characterization of the *Cln3<sup>Δex7-8</sup>* Retina and Immunohistological Evaluation of Müller and Microglia Cells.

In order to determine the severity and/or presence of retinal degeneration in the *Cln3<sup>Δex7-8</sup>* model, mice were studied starting at 18 months of age. This time point would ensure detection of retinal degeneration, if present. Retinal sections of 18 month old *Cln3<sup>Δex7-8</sup>* and wild type mice were first stained with hemotoxylin-eosin (HE) for morphological comparison (Fig. 6 A ). Both retinas appeared to have identical striated retinal morphology with no observable change in the photoreceptor or inner and outer nuclear layers (PR, INL and ONL, respectively). These results point towards no obvious morphological degeneration in the *Cln3<sup>Δex7-8</sup>* retina.

The presence and morphology of glial cells was determined as well. Retinal sections of 18 month old *Cln3<sup>Δex7-8</sup>* and wild type were stained with GFAP and Iba1, markers for Müller cells and microglia, respectively. *Cln3<sup>Δex7-8</sup>* retinas show up-regulated GFAP expression seen as fluorescent columns spanning the retina, indicative of reactive Müller cells (Fig. 6 B ). In contrast, wild type retinas showed mostly end-feet signalling in the ganglion cell layer (GCL) with few retinal spanning strands normally associated with healthy aging retina.

**Figure 5. Histological and immunohistological evaluation of 18 month old *Cln3*<sup>Δex7-8</sup> retina, Müller cells and microglia.** A. Histological comparison of retinal layers in 18 month old (M) wild type (*Cln3*<sup>+/+</sup>) and *Cln3*<sup>Δex7-8</sup> retina with hematoxylin-eosin (HE) stain. B. Immunolabelling of reactive Müller cells with GFAP antibody. C. Immunolabelling of microglia cells with Iba1 antibody. D. Auto-fluorescent accumulation of lipofuscin deposits in wild type and *Cln3*<sup>Δex7-8</sup> retinas. E. Merged images of Iba1-labeled microglia with auto-fluorescent lipofuscin deposits. Arrow indicates co-localization of lipofuscin and microglial cell. E. Iba1-labeled flat-mounts, encompassing the plexiform layers, reveal different microglia morphology in wild type and *Cln3*<sup>Δex7-8</sup> retinas. PR, photoreceptors; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 50μM.

Iba1 staining of microglia revealed morphologically ramified cells in the inner and outer plexiform layers (IPL and OPL, respectively) of wild type retinas, where resting retinal microglia are normally found (Fig. 6 C). In contrast, *Cln3*<sup>Δex7-8</sup> retinas showed migrating amoeboid microglia with little ramifications normally associated active microglia. Auto-fluorescent ceroid lipofuscin deposit were detected as bright roundish signals found throughout the *Cln3*<sup>Δex7-8</sup> retina (Fig. 6 D). Wild type retinas had little or no storage material in comparison. Microglia were also observed engulfing lipofuscin deposits as shown by co-localization of Iba1 signal with auto-fluorescent signal (Fig. 6 E). Furthermore, flat mount stainings of microglia with Iba1 as a method of better assessing microglia morphology (Fig 6 F), showed long ramified microglia in wild type retinas, compared to rounder, more alert microglia seen in the *Cln3*<sup>Δex7-8</sup> retinas.

As Müller cells and microglia appear to be active in 18 month old *Cln3*<sup>Δex7-8</sup> retinas, 12 month old mutant retinas were also studied (Fig. 7 ). HE stains showed no morphological differences to age-matched wild type retinas (Fig. 7 A) . GFAP stains showed the presence of active Müller cells (Fig. 7 B). Sections stained with Iba1 showed ramified microglia in the IPL and OPL as did flat mounts (Fig. 7 C, F ). Auto-fluorescent lipofuscin deposits could be seen throughout the retina (Fig. 7 D).

These data indicate microglia activation occurs at a later time point in the *Cln3<sup>Δex7-8</sup>* retina contrary to reactive Müller cells which are first seen starting at 6 months (data not shown).

**Figure 6. Histological and immunohistological evaluation of 12 months old *Cln3<sup>Δex7-8</sup>* retina, Müller cells and microglia.** A. Histological comparison of retinal layers in 12 month old wild type and *Cln3<sup>Δex7-8</sup>* retina with HE stain. B. Immunolabelling of reactive Müller cells with GFAP antibody. C. Immunolabelling of microglia cells with Iba1 antibody. D. Auto-fluorescent accumulation of lipofuscin deposits in retinas. E. Merged images of Iba1-labeled microglia with auto-fluorescent lipofuscin deposits/ F. Iba1-labeled flat-mounts, reveal similar microglia morphology in wild type and *Cln3<sup>Δex7-8</sup>* retinas. M, months; HE, hemotoxylin-eosin; PR, photoreceptors; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 50μm

### 4.1.2 Functional Characterization of the *Cln3<sup>Δex7-8</sup>* Retina

To assess changes in visual acuity or retinal function in the *Cln3<sup>Δex7-8</sup>* mouse, optokinetic tracking (OKT) and electroretinogram (ERG) measurements were performed. These experiments indicate if any kind of retinal degeneration exist in this mouse model which is not obvious using morphological studies. Wild type and *Cln3<sup>Δex7-8</sup>* mice were tested at different ages in order to temporally assess degeneration.

#### 4.1.2.1 Optomotry Assessment of Visual Acuity

Visual acuity of *Cln3<sup>Δex7-8</sup>* and wild type mice was studied using OKT measurements in an OptoMotry system. OKT is a reliable method for measuring mouse visual acuity by tracking head and neck movements in response to gratings projected on a virtual cylinder. Acuity is quantified by increasing the spatial frequency of the grating until a tracking response can no longer be elicited. OKT measurements of aging *Cln3<sup>Δex7-8</sup>* and age-matched wild type mice were done every two

months starting at one month of age until 18 months. (Fig. 8) Wild type mice maintained normal OKT thresholds between 0.27 and 0.3 c/d (cycles per degree) at all ages measured. *Cln3<sup>Δex7-8</sup>* mice had relatively normal OKT thresholds until 12 months of age, with slight decline starting at nine months of age. Past 12 months, OKT thresholds declined faster until 0.4 c/d at 18 months of age, indicating almost complete loss of vision. Due to the individual nature of the disease, the standard deviation was variable at each measured time point. These results indicate *Cln3<sup>Δex7-8</sup>* mice suffer from progressive visual failure which is accelerated past 12 months of age.

**Figure 7. Optokinetic tracking measurement of visual acuity using the OptoMotor system in *Cln3<sup>Δex7-8</sup>* and wild type mice.** Changes in optokinetic tracking thresholds (cycles/degree) is plotted against age in months representing temporal change in visual acuity for both wild type and *Cln3<sup>Δex7-8</sup>* mice. Mean value  $\pm$  SD is shown. n= 5-9

#### 4.1.2.2 Electroretinograms Measurements of Photoreceptors and Inner Retina

ERG experiments and data analysis were performed by Dr. med Cornelia Volz and Prof Dr. med. Herbert Jägle from the University Eye Clinic Regensburg. ERG measurements were performed on dark adapted (scotopic) *Cln3<sup>Δex7-8</sup>* and wild type mice at 6, 12 and 18 months of age (Fig. 9). Rod photoreceptor function was measured by the amplitude and implicit time of the leading trough of the response wave (a-wave) whereas the inner retinal function was measured by amplitude and implicit time of the positive peak wave (b-wave). At 6 months of age, both wild type and *Cln3<sup>Δex7-8</sup>* mice had relatively similar a- and b-wave measurements (Fig. 9 A). At 12 months, the a-wave of the *Cln3<sup>Δex7-8</sup>* mice had a lower negative drop compared to age-matched wild types, indicating decreased photoreceptor function. The b-wave in these mice also had a decreased positive amplitude, indicating a degeneration in the inner retinal cells. These differences were most striking at high flash intensities. Noteworthy, the decreased measurements of the b-wave was greater than the a-wave indicating a larger change in the inner retina compared to photoreceptors. 18 month

*Cln3<sup>Δex7-8</sup>* mice showed further degeneration of the a-wave which became obvious at high flash intensity. In contrast, the b-wave of these mice was severely decrease in amplitude at all flash intensities, indicating severe degeneration of the inner retinal function. There was no difference in implicit time between wild type and *Cln3<sup>Δex7-8</sup>* mice at 6 and 12 months of age (Fig. 9 B). At 18 month, the *Cln3<sup>Δex7-8</sup>* a-wave implicit time was longer at most flash intensities compared to wild type. A graph plotting the b-/a-wave ratio (Fig. 9 C) highlights the lowered b-/a-wave ratio of *Cln3<sup>Δex7-8</sup>* mice compared to wild type starting at 12 months of age, indicative of greater degeneration in the b-wave compared a-wave.

**Figure 8. Dark adapted (scotopic) ERG response of wild type and *Cln3<sup>Δex7-8</sup>* mice at 6, 12 and 18 months of age. A-C. Changes in a-wave and b-wave amplitudes, implicit response time and b/a-wave amplitude ratio from low to high flash intensity. Each symbol represents the mean value of minimum three mice  $\pm$  SD. Data analysis and graphs were made by Prof. Dr. Herbert Jägle and are used with his consent.**

Interestingly, the aging wild type also show a change in a- and b-wave amplitude as they age. Amplitudes decrease by one third from 6 months to 18 months, which is too high to be attributed to aging. Upon further speculation, this decrease was attributed to the presence of the *Crb1<sup>rd8</sup>* mutation (section 4.1.3).

#### **4.1.3 *CRB<sup>rd8</sup>* Mutation present in the *Cln3<sup>Δex7-8</sup>* and Wild Type Background**

Mattapallil et al. reported the existence of the *Crb1<sup>rd8</sup>* mutation in the C57BL/6N genetic background, which could confound retinal function studies in transgenic mouse models established on that background (Mattapallil et al., 2012). The *Cln3<sup>Δex7-8</sup>* and corresponding wild types were all of the C57BL/6N background and all tested positive for the *Crb1<sup>rd8</sup>* mutation via sequencing.

#### **4.1.4 End of *Cln3<sup>Δex7-8</sup>* Study**

Due to the presence of the *Crb1<sup>rd8</sup>* mutation as well as the lack of morphological degeneration and early microglia activation, further studies on the *Cln3<sup>Δex7-8</sup>* mouse model were discontinued.

### **4.2 Characterization of the *Cln6<sup>nclf</sup>* Retina**

The second NCL model studied was the *Cln6<sup>nclf</sup>* mouse model. Localized microglia and astrocyte activation were previously reported in brain studies done on CLN6 mutant sheep model (Oswald et al., 2005) and *Cln6<sup>nclf</sup>* mouse model (Bronson et al., 1998; Thelen et al., 2012). Initial studies done by Bronson et al. also showed severe retinal degeneration in the *Cln6<sup>nclf</sup>* mouse model starting at four months with complete loss of retina by nine months (Bronson et al., 1998). The role microglia, Müller cells and inflammation play in this degeneration have not previously been studied. Of note, *Cln6<sup>nclf</sup>* and corresponding wild types were tested negative for *Crb1<sup>rd8</sup>* mutation.

#### **4.2.1 Morphological Characterization of the *Cln6<sup>nclf</sup>* Retina**

Temporal retinal degeneration and glial activation in *Cln6<sup>nclf</sup>* mice was studied at different ages, starting at one month and ending at eight months of age. Histological changes in retina were analyzed using a fuchsin/methylene blue dye on 1 µm thick sections (Fig. 10). Retinal sections showed a progressive degeneration of all retinal layers in *Cln6<sup>nclf</sup>* mice compared to wild-type

controls starting at four months (Fig. 10 A). At eight months of age, the photoreceptor cell layer in particular was heavily compromised in *Cln6<sup>nclf</sup>* retinas with only a few rows of cell nuclei remaining.

Next, the glial status in the retina was assessed. Müller glia cells were detected using GFAP as a marker (Fig. 10 B). Wild type eight month old mice had some filamentous but mostly end-feet GFAP staining associated with normal aging retinas. One month old *Cln6<sup>nclf</sup>* mice showed increase GFAP staining which became more intense by four months onwards. Increased GFAP expression at early ages in *Cln6<sup>nclf</sup>* mice indicates reactive Müller cell gliosis as a prominent early event in retinal degeneration.

Retinal sections were also stained with the microglia marker Iba1 to assess changes in microglial morphology and migration into different layers (Fig. 10 C). Wild type microglial cells were seen in a non-alert ramified form in the IPL and OPL. In contrast, one month old *Cln6<sup>nclf</sup>* retinas already had amoeboid microglia cells with protrusions reaching into the nuclear cell layers. At four, six and eight months of age, bloated microglia infiltrating the nuclear layers could be detected, indicating fully alert and active microglia. Lipofuscin deposits were seen in photoreceptor and inner-retinal layers as early as one month in *Cln6<sup>nclf</sup>* mice and increased in number with age (Fig. 10 D). Alert phagocytic microglial cells often co-localized with auto-fluorescent lipofuscin deposits suggesting phagocytoses of large amounts of auto-fluorescent material (Fig. 10 E, arrowheads). To further confirm the morphological transition of ramified microglia cells into large phagocytes, retinal flat-mounts were stained with Iba1 (Fig 10 F). Retinal flat-mounts from wild-type mice displayed a highly ramified microglia network. In contrast, one month old *Cln6<sup>nclf</sup>* retinas already showed a mixed population of ramified and phagocytic microglia. As the mice aged, the cells became rounder in shape with shorter protrusions, indicating a loss of the ramified network structure and an alerted state.

**Figure 9. Histological and immunohistological characterization of wild type and aging *Cln6<sup>ncif</sup>* mouse retina.** A. Histological changes in retina sections from 8 month old wild type mice compared to 1,4,6 and 8 month old *Cln6<sup>ncif</sup>* mice using fuchsin/methylene (F/M) blue staining. B. Immunolabelling of reactive Müller cells in wild type and aging *Cln6<sup>ncif</sup>* retinas using anti-GFAP antibody. C. Staining of microglial cells in anti-Iba1 antibody. D. Auto-Fluorescent lipofuscin accumulation in wild type and *Cln6<sup>ncif</sup>* retinas. E. Merged images of anti-Iba immunolabelling with auto-fluorescent lipofuscin deposits. White arrowheads indicate co-localization of lipofuscin with microglial cells. F. Anti-Iba1 labelled retinal flat-mount reveal different microglial morphologies in wild type and *Cln6<sup>ncif</sup>* retinas. The thickness of the flat-mount is indicated on the sides of the images. OS, outer segments; IS, inner segments; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 50 μm.

## 4.2.2 Quantification of Retinal Degeneration

Histological experiments done on *Cln6<sup>ncif</sup>* retinas showed progressive degeneration of cell layers, however the rate of cell death and which layers (if any) were more affected was unclear. TUNEL assays were performed to assess and quantify in which layers cell death was occurring. Retinal morphometry experiments were done to quantify shrinking of total retinal and photoreceptor thickness.

### 4.2.2.1 TUNEL Assay

TUNEL assays identify which cells are undergoing apoptosis by labeling fragmented DNA strands. Cross-sections from six month old wild type as well as one and six month old *Cln6<sup>ncif</sup>* retinas underwent TUNEL reaction and the labeled cells visualized (Fig. 11). Wild type retinas had only a few TUNEL positive cells. One and six month *Cln6<sup>ncif</sup>* retinas, showed numerous but equal number of TUNEL positive cells located mostly in the ONL. Since *Cln6<sup>ncif</sup>* retinal degeneration is progressive, cells are constantly undergoing apoptosis, which is why approximately the same number of cells can be identified by TUNEL assay at any given time. For this reason, TUNEL positive cells were not quantified.

**Figure 10. TUNEL stains of *Cln6<sup>+/+</sup>* and *Cln6<sup>ncif</sup>* retinas.** Apoptotic cells in the retina were detected using *in situ* detection of fragmented DNA strands (TUNEL assay). A-C. TUNNEL stain of 6 month old wild type retinas were compared to 1 and 6 month old *Cln6<sup>ncif</sup>* retinas. PR, photoreceptors; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 50μM

### 4.2.2.2 Retinal Morphometry

As an alternative method of quantifying progressive cell death, retinal morphometric analyses was performed. This method allows measurement of total or specific cell layers of the retina making it possible to evaluate the progression of cell death as well shrinking of specific layers. Morphometric analysis were performed on 1  $\mu\text{m}$  thick retinal sections previously embedded in Epon. Whole retina and photoreceptor membrane thickness of one, four, six and eight month old *Cln6<sup>ncf</sup>* and wild type mice were measured (Fig 12). Whole retinal measurements indicated changes already occurred in the central retina of one month old *Cln6<sup>ncf</sup>* mice and this effect steadily increased with disease progression throughout the whole retina (Fig. 12 A ). Measuring the Outer and Inner Segment (OS and IS, respectively) of the photoreceptors showed a drastic decrease in thickness between four and six months, contrary to the steady decrease seen in total retinal thickness (Fig. 12 B). This marked decrease in photoreceptor membrane thickness coincides with the time point when microglia markedly changed their phenotype.

**Figure 11. Retinal morphometry measurements of *Cln6<sup>+/+</sup>* and *Cln6<sup>ncf</sup>* whole retina and photoreceptor membrane.** Anterior and posterior retinal areas were divided into ten sections using the optic nerve head as a central reference. The thickness of total retina and outer/inner segment of photoreceptors was measured and plotted. A. Quantification of whole retinal thickness of *Cln6<sup>ncf</sup>* retinas compared to wild type controls. B. Quantification of photoreceptor layer thickness compared to wild type control. The mean value  $\pm$  SD is plotted.  $n=4$  animals per age group. *Cln6<sup>ncf</sup>* measurements were statistically compared to age-matched controls using two-way ANOVA followed by Bonferroni post-test. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

### 4.2.3 Behavioural and Functional Characterization of the *Cln6<sup>nclf</sup>* Retina and Mouse Model

Functional retinal studies to understand the depth of retinal degeneration in the *Cln6<sup>nclf</sup>* model were done using OKT and ERGs. Furthermore, possible motor problems exhibited by the *Cln6<sup>nclf</sup>* mice which could interfere with OKT measurements were also assessed using Rotarod measurements.

#### 4.2.3.1 Optokinetic Tracking

OKT measurements using an OptoMotor system were done on wild type and *Cln6<sup>nclf</sup>* mice monthly, starting at one month of age and ending at eight months of age (Fig. 13). Wild-type mice had a relatively stable maximal OKT threshold at 0.3 c/d. *Cln6<sup>nclf</sup>* mice also showed normal OKT thresholds up to four months of age which declined slowly, but not significantly. However, starting at five months of age, *Cln6<sup>nclf</sup>* mice appeared to have a significant and rapid decline in OKT thresholds with 0.05 c/d by eight months of age. The large variability of OKT thresholds in older animals most likely reflects variable disease progression in *Cln6<sup>nclf</sup>* mice.

**Figure 12. Optokinetic tracking measurement of aging wild type and *Cln6<sup>nclf</sup>* mice.** Mouse visual acuity was measured via OKT in an OptoMotor system. Changes in OKT threshold (cycle/degree) is plotted against age in months. Mean value  $\pm$  SD is shown.  $n = 12$  animals per age group. *Cln6<sup>nclf</sup>* measurements were statistically compared to age-matched controls using two-way ANOVA followed by Bonferroni post-test. \*\*\* $p < 0.001$ .

#### 4.2.3.2 Rotarod Performance

To clarify if the progressive decline in visual acuity was indeed due to vision loss and not motor-neuron deficits, which could also influence OKT readings, rotarod experiments were performed

(Fig. 14). Mice were subjected to rotarod experiments with three trials per day for two consecutive days. The performances from both days were compared to determine if mice had improved rotarod performance. All mice tested showed a significant improvement on the second day of rotarod testing indicating that they had normal learning abilities. However, contrary to four and six month old mice which all show approximately the same rate of improvement, eight month old *Cln6<sup>ncif</sup>* mice had a significantly reduced improvement rate compared to age-matched wild type mice. This indicates that older *Cln6<sup>ncif</sup>* mice have a reduced cognitive function and/or motor impairment. It has been previously reported that these mice start having motor problems at approximately eight months of age (Bronson et al., 1998). These results indicate that the decrease in OKT measurements from four to six months seen in the *Cln6<sup>ncif</sup>* mice is indeed due to a loss of visual acuity and is most likely not affected by motor problems.

**Figure 13. Rotarod performance of wild type and *Cln6<sup>ncif</sup>* mice aged 4, 6 and 8 months.** Mouse rotarod performance was tested three times on two subsequent days (Day 1 and 2). The average performance of wild type mice on day 2 along with *Cln6<sup>ncif</sup>* performance on both days were normalized to wild type performance on day 1. Statistical changes in performance from day 1 to 2 for each group along with day dependent differences between control and *Cln6<sup>ncif</sup>* was calculated using Kruskal-Wallis ANOVA. n=6-15 animals per age group. \*\*\**p* < 0.001.

#### 4.2.3.3 ERG Measurements of Retinal Function

ERG experiments were done as mentioned above (section 4.1.2.2) on dark adapted aging *CLN6<sup>ncif</sup>* and age-matched wild types (Fig. 15). The a-wave amplitude was significantly decreased in one month *Cln6<sup>ncif</sup>* mice at most flash intensities and progressively decreased until eight months where almost no response is recorded (Fig. 15 A). B-wave amplitudes significantly differ from age-matched controls starting at three months with very little response present at eight months. Wild type mice showed a normal mild decrease in both a- and b-wave amplitudes with age. The implicit time was not significantly different at most ages compared to controls and was slightly higher in eight month old *Cln6<sup>ncif</sup>* mice in both the a- and b-wave (Fig. 15 B). Lastly, the b-/a-wave amplitude

ratio was higher for *Cln6<sup>nclf</sup>* mice starting at one month of age, indicating an early photoreceptor-dominated degeneration followed by an inner retinal degeneration (Fig. 15 C).

**Figure 14. Dark adapted (scotopic) ERG response amplitudes, implicit times and b/a-wave amplitude ratios of age-matched wild type and *Cln6<sup>nclf</sup>* mice.** A-C. Response amplitude of a- and b-wave, implicit response time of a- and b-wave as well as b/a-wave ratio were plotted from low to high intensity for 1 and 8 month old wild type, and *Cln6<sup>nclf</sup>* mice aged 1 to 8 months. Each symbol represents the mean of three animals  $\pm$  SEM. For the brightest flash intensity, mean amplitude values of *Cln6<sup>nclf</sup>* mice and age-matched controls were compared with ANOVA. a-wave: 1 month:  $p=0.0048$ , 2 months:  $p=0.0005$ , 3 to 8 months:  $p<0.0001$ . b-wave: 1 month:  $p=0.245$ , 2 months:  $p=0.059$ , 3 to 8 months:  $p<0.0001$ . Data analysis and graphs were made by Prof. Dr. Herbert Jägle and are used with his consent.

#### 4.2.4 Transcriptional Changes in Stress and Inflammatory Gene Markers in the *Cln6<sup>nclf</sup>* Retina

Quantitative real-time RT-PCR was used to identify whether progressive retinal degeneration in *Cln6<sup>nclf</sup>* mice is connected with cell death, stress response and inflammation. Whole retina from aging *Cln6<sup>nclf</sup>* mice and age-matched wild types (ages one to eight months) were examined for transcriptional marker expression changes (Fig 16). Experiments were carried out in duplicates and analyzed using  $\Delta\Delta CT$  relative quantification. Age-matched wild types were used as calibrators and adenosine triphosphatase (ATPase) as a reference.

First, NCLF mRNA levels were determined to study a potential nonsense-mediated decay of mutant mRNA. At all analyzed time points, NCLF transcript levels were significantly reduced in *Cln6<sup>nclf</sup>* retinas (Fig. 16 A ), indicating that ER-stress pathways could be active in mutant cells. At all ages tested, *Cln6<sup>nclf</sup>* retinas had half the amount of NCLF mRNA compared to wild type. Next, apoptotic and inflammatory markers were studied via CD95 and tumor necrosis factor-alpha (TNF $\alpha$ ),

respectively. CD95 expression (also known as Fas receptor) was increased six to seven fold at one and six months in *Cln6<sup>nclf</sup>* retinas (Fig. 16 B). At other ages, CD95 expression was on average two fold higher in *Cln6<sup>nclf</sup>* retinas but was not determined to be significant. TNF $\alpha$  had increased expression at all aged test but was significantly increased at eight months (Fig. 16 C). GFAP mRNA levels, expressed by reactive Müller cells, were increased five to ten fold in *Cln6<sup>nclf</sup>* mice at all ages, correlating to the immunohistochemical experiments shown above (Fig. 16 D). Photoreceptor stress marker, endothelin 2 (EDN2) was strongly up-regulated in *Cln6<sup>nclf</sup>* retinas at all ages, indicating a prominent stress response at all ages (Fig 16 E). Next, classical microglia markers: CD68, early growth response 1 (EGR1) and complement C1q subunit a (C1qa) were assessed. CD68 expression was significantly higher in one and six month old *Cln6<sup>nclf</sup>* with approximately two-fold increased expression at other ages (Fig. 16 F). EGR1 transcript levels were increase four to five fold between one and three month of age with expression levels increasing to 12-fold and higher starting at four months in *Cln6<sup>nclf</sup>* retinas (Fig. 16 G). Finally, C1qa expression levels were significantly increased at all ages (Fig. 16 H). These experiments suggest that retinal degeneration in *Cln6<sup>nclf</sup>* retinas follows a temporally ordered sequence of very early cell stress associated with increased immune response.

**Figure 15. Quantitative real-time RT-PCR expression analysis of *Cln6<sup>nclf</sup>* retinas compared to age-matched wild type controls.** Relative mRNA levels were analyzed for NCLF (A), CD95 (B), TNF $\alpha$  (C), GFAP (D), EDN2 (E), CD68 (F), EGR1 (G) and C1Qa (H). mRNA expression was normalized to the reference gene *Atp5b* and graphed relative to age-matched wild-type ( $\pm$  SD).  $n=7-10$  animals per age. Age-matched expression was compared using two-way ANOVA followed by Bonferroni post test. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

### 4.3 CLN6<sup>nclf</sup> Dietary Supplementation Study

Numerous studies show natural dietary compounds are able to target microglial pathways reducing inflammatory processes whilst simultaneously supporting neuronal survival. Based on *in vivo* and *in vitro* studies which showed significant changes in microglia transcription profile, attenuation of activated microglia and decreased neuronal degeneration, three natural compounds were selected for this supplementation study: curcumin, luteolin and docosahexaenoic acid (DHA). *Cln6<sup>nclf</sup>* mice received standard chow or chow supplemented with 0.6% curcumin, 0.6% luteolin or 5% DHA for thirty weeks directly after weaning (post natal day 21-23). The study ended when the

mice were seven months old. Mice were weighed weekly to ensure proper and comparable development (Fig. 17).

**Figure 16. Weekly body weight of control-fed and supplemented mice.** Wild type body weight is plotted only at 30 weeks. n=12 animals per group.

#### 4.3.1 Supplementation effect on *Cln6<sup>nclf</sup>* Retinal Histology and Microglia

Histological comparison of control-fed and supplemented retinas were done as previously described (section 4.2.1) (Fig. 18). Supplemented retinas had generally better preserved photoreceptor and ONL thickness (Fig. 18 A). The OS of the photoreceptor layers appeared to be thicker compared to control retinas, particularly in DHA supplemented retinas. The ONL of control retinas comprised of 4 cell layers compared to the 5-6 layers found in curcumin and luteolin supplemented retinas and 7-8 layers in DHA supplemented retinas. GFAP staining revealed the presence of reactive Müller cells in all retinas (Fig. 18 B). The shape and location of microglia as seen by Iba1 staining as well as auto-fluorescent lipofuscin deposits were also comparable in control-fed and supplemented mice (Fig. 18 C, D). Retinal flat-mounts stained with Iba1 as a method for analyzing microglial morphology revealed different microglial phenotype between control and supplemented retinas (Fig. 18 F). Amoeboid microglia with almost not ramifications were observed in control retinas, whilst curcumin, luteolin and DHA supplemented retinas had highly ramified microglia within an intact network.

**Figure 17. Histological and immunohistological comparison of control-fed mice supplemented with 0.6% curcumin, 0.6% luteolin and 5% DHA.** A. Histological comparison of control animals and supplemented retinas using fuchsin/methylene blue stain. B. Immunolabelling of Müller cells with anti-GFAP antibody C. Staining of microglial cells with anti-Iba1 antibody. D. Auto-fluorescent lipofuscin accumulation in wild type and *Cln6<sup>retif</sup>* retinas. E. Merged images of anti-Iba1 immunolabelling with auto-fluorescent lipofuscin deposits. F. Anti-Iba1 labeled retinal flat mounts reveal ramified microglia compared to control retinas. The thickness of the flat-mount is indicated on the sides of the image. OS, outer segments; IS, inner segments; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar, 50  $\mu$ m.

### 4.3.2 Retinal Morphometry of Supplemented Retinas

Histological analysis revealed a better preserved retinal morphology in supplemented retinas compared to control. These findings were verified by quantifying the OS and IS length of photoreceptors and total retinal thickness using morphometric analysis (Fig. 19). Both curcumin and luteolin supplemented retinas had approximately the same total retinal thickness and slightly increase photoreceptor thickness which was not significant compared to controls. In contrast, DHA

supplemented mice had non-significant increase in total retinal thickness and a significant increase in photoreceptor thickness.

**Figure 18. Retinal morphometry measurements of total retina and photoreceptor membrane layer.** Anterior and posterior retinal areas were divided into ten sections using the optic nerve head as a central reference. The thickness of total retina and outer/inner segment of photoreceptors was measured and plotted. A. Quantification of whole retinal thickness of curcumin, luteolin and DHA-supplemented versus control retinas. B. Quantification of the photoreceptor layer. Mean value  $\pm$  SD is plotted. Supplemented groups were compared to control using two-way ANOVA followed by Bonferroni post-test.  $n = 5$  animals per group. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$

### 4.3.3 Retinal Function of Supplemented Retinas

Although supplementation was shown to have some effects on preserving retinal morphology as well as attenuating microglial morphology, whether these effects translated to better vision remained unclear. Thus, OKT and ERG measurements were performed.

#### 4.3.3.1 OKT Measurements of Supplemented Retinas

OKT measurements of both control and supplemented *Cln6<sup>nclf</sup>* mice were done monthly (Fig. 20). As seen previously, non-supplemented *Cln6<sup>nclf</sup>* mice had slight decrease in visual acuity up to four months of age after which decline became more rapid. By seven months, control mice have an OKT threshold of 0.06 c/d. Mice supplemented with curcumin and DHA both had higher visual acuity compared to control mice starting at three months of age onwards. At seven months, curcumin supplemented mice had an OKT threshold of 0.156 c/d whereas DHA had an OKT threshold of 0.139 c/d. Luteolin supplemented mice had uneven OKT measurements until four months of age after which thresholds became significantly better than controls. At seven month, mice had an average OKT threshold of 0.19 c/d.

**Figure 19. Optokinetic tracking of control and supplemented mice.** Visual acuity of control and supplemented mice was measured monthly. Changes in OKT threshold (cycle/degree) is plotted against age in months. Mean value  $\pm$  SD is shown.  $n = 12$  animals per age group. Supplemented measurements were statistically compared to controls using two-way ANOVA followed by Bonferroni post-test. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$

#### 4.3.3.2 ERGs of Supplemented Retinas

ERGs were done on dark adapted seven month old control and supplemented mice (Fig. 21). A-wave amplitudes were increased in all supplemented retinas at higher flash intensities compared to control. Amplitudes difference were significant in curcumin and DHA supplemented retinas at highest flash intensity. B-wave amplitudes were also increased for all supplemented retinas compared to control and were also considered significant at highest flash intensity. These data indicate a preservation of both the photoreceptor and inner-retinal function. Curcumin and luteolin supplemented retinas had similar a- and b-wave implicit time compared to control retinas. In contrast, DHA supplemented retinas had shorter implicit time for both a- and b-wave at higher flash intensities, which is consistent with less severe retinal degeneration. The b/a-wave ratio of both luteolin and curcumin supplemented retinas was similar to control retinas. DHA supplemented retinas had lower b/a-wave ratio at higher flash intensities, indicating a stronger change in the a-wave compared to b-wave.

**Figure 20.** Dark adapted ERG response amplitude, implicit time and b/a-wave amplitude ratio of age-matched *Cln6<sup>nclif</sup>* control and supplemented mice. A-C. Response amplitude of a- and b-wave, implicit response time of a- and b- wave as well as b/a-wave ratio were plotted from low to high intensity for control and curcumin, luteolin, DHA-supplemented mice at seven months of age. Each symbol represents the mean of 6 animals  $\pm$  SEM. Statistical comparison of supplemented response vs. control response was done using two-way ANOVA for the amplitudes of the highest flash intensity. Amplitude: a-wave:  $p=0.002$ ,  $p=0.128$  and  $p<0.0001$ , b-wave:  $p=0.028$ ,  $p=0.0147$   $p=0.009$  for curcumin, luteolin and DHA, respectively. Implicit time: a-wave:  $p=0.77$ ,  $p=0.0983$  and  $p=0.0002$ , b-wave:  $p=0.0004$ ,  $p=0.159$  and  $p<0.0001$  for curcumin, luteolin and DHA, respectively. Data analysis and graphs were made by Prof. Dr. Herbert Jägle and are used with his consent.

#### 4.3.4 Transcriptional changes affected by Supplementation

Quantitative real-time RT-PCR comparing whole supplemented retinas to non-fed retinas were done as previously described (section 4.2.4) (Fig. 22). Seven month wild type retinas were also included and compared to non-fed retinas as an additional experimental control. Markers related to stress, inflammation and apoptosis were analyzed.

First, mRNA levels of NCLF were analyzed to see if supplementation effected non-sense mediated decay (Fig. 22 A). Supplemented retinas had approximately the same level of NCLF expression as control retinas. Wild types retinas had approximately two-fold NCLF expression, in concordance to experiments done in section 4.2.4. Apoptosis marker, caspase 8 was significantly reduced in DHA supplemented and wild type retinas compared to non-fed retinas (Fig. 22 B). A similar profile was also seen for CD95 (Fig. 22 C). Reactive Müller cell marker, GFAP, was also significantly reduced in DHA supplemented and wild type retinas (Fig. 22 D). This is in contrast to the immunohistochemical staining seen above (Fig. 18 B). However, it is possible that the GFAP antibody is sensitive enough to detect slightest increase in GFAP expression. END2 expression remained the same for supplemented retinas and control with significantly lowered expression in wild type retinas (Fig. 22 E).

**Figure 21. Quantitative real-time RT-PCR expression analysis of curcumin, luteolin, DHA-supplemented retinas compared to control.** Relative mRNA levels were analyzed for NCLF (A), Caspase 8 (B), CD95 (C), GFAP (D), EDN2 (E), CD68 (F), C1Qa (G) and TGFβ (H). Supplemented and wild type mRNA expression was normalized to the reference gene *Atp5b* and graphed relative to control expression ( $\pm$  SD).  $n = 5$  animals per age. Age-matched expression was compared using one-way ANOVA followed by Bonferroni post test. \* $p < 0.05$ ; \*\* $p < 0.01$ ; \*\*\* $p < 0.001$ .

Classical microglia marker CD68 was significantly increased in DHA supplemented retinas, as was as C1qa (Fig. 22 F, G). As shown before, C1qa levels were significantly decreased in wild type retinas. Finally, Tgfβ1 (Transforming growth factor beta), a marker for alternatively activated microglia associated with tissue repair and neuroprotection was significantly decreased in wild type retinas, as expected, as well as DHA supplemented retinas (Fig. 22 H). These data imply curcumin and luteolin had very little effect at the transcriptional level, whereas DHA supplementation had positive effects on apoptotic markers and mixed effects on microglia marker expression.

## 5. Discussion

### 5.1 Comparison of retinal Degeneration in NCL Models

Loss of vision is an early symptom in most forms of human NCL, indicating the retina is highly vulnerable to NCL pathologies (Haltia and Goebel, 2012). However, since patients present vision problems long before neurological symptoms emerge, they are often misdiagnosed with maculopathies (Birch, 1999) leading to a lack of information of how retinal degeneration in NCL progresses or if specific biomarkers are present. As such, naturally occurring and genetically modified animal models of NCL have greatly improved understanding of early disease pathology in patients. In many instances, NCL mice recapitulate typical clinical and histopathological features of patients including vision loss, neuro-motor deficits and storage of ceroid lipofuscin material in lysosomes (Shacka, 2012). Unfortunately, the little research which has been dedicated to studying retinal degeneration in NCL models has led to a large gap in the knowledge of retinal phenotype.

The first part of this thesis focused on characterizing retinal degeneration in two mouse models of NCL: *Cln3<sup>Δex7-8</sup>*, a model for juvenile NCL, and *Cln6<sup>nclf</sup>*, a model for late-infantile NCL. Upon initial comparison of both models, it becomes obvious that *Cln6<sup>nclf</sup>* mice have a far more severe retinal phenotype starting at four months of age compared to the *Cln3<sup>Δex7-8</sup>* model which is relatively normal until nine months of age. Histology and morphometry data showed thinning of the nuclear layers in *Cln6<sup>nclf</sup>* retinas already started at one month of age and progressed until only a few cell layers were present in the ONL. This course of retinal degeneration is principally consistent with preliminary observations of the initial report describing the *nclf* phenotype in the Jackson lab (Bronson et al., 1998). However, data from this study showed degeneration of the outer retina clearly preceded cell death in the inner retina, implicating that photoreceptor cells are very early affected during disease progression. In contrast, *Cln3<sup>Δex7-8</sup>* retinas retained cell layers, even at 18 months of age, with no obvious inner or outer retinal degeneration.

Both retinas did show a large accumulation of auto-fluorescent deposits with age. Accumulation of fluorescent storage material has been also reported in the visual cortex and retina of CLN6 mutant sheep and other animal models (Oswald et al., 2005; Katz et al., 2011). In mice, retinal auto-fluorescence has been shown for *Ppt1<sup>-/-</sup>* (Lei et al., 2006) and the spontaneous *Cln8<sup>mnd</sup>* (*motor neuron degeneration*) mouse model (Seigel et al., 2005). *Ppt1<sup>-/-</sup>*, a CLN1 mutant mouse model of

infantile NCL, present large amounts of yellow-emitting auto-fluorescent storage bodies from four to eight months of age with mild changes in retinal morphology (Lei et al., 2006). In contrast, retinal auto-fluorescence in *Cln8<sup>md</sup>* animals is already evident at birth and photoreceptor loss begins at postnatal day 15 (Messer et al., 1993; Seigel et al., 2005). In this regard, *Cln8<sup>md</sup>* and *Cln6<sup>ncl</sup>* mice are similar. Accumulation of lipofuscin deposits have also been reported *abcr*<sup>-/-</sup> mice, a mouse model for Stargardt's disease, a juvenile form of maculopathy (Weng et al., 1999). In this model, the outer segments of the photoreceptor are shortened, as seen in the *Cln6<sup>ncl</sup>* retina, indicating that accumulation of lipofuscin may cause impairment in the RPE resulting in inability to properly maintain photoreceptor membrane homeostasis (Mata et al., 2001).

OKT measurements of *Cln3<sup>Δex7-8</sup>* mice showed slow decline in visual acuity starting at nine months with rapid decline occurring past 12 months of age resulting in severe vision impairment at 18 months. Electroretinogram measurements at six months were normal, at 12 months there was a mild decrease in b-wave response, and at 18 months a significant reduction was seen in both a- and b-wave (photoreceptors and inner retina, respectively). These data are concurrent with OKT measurements. ERG investigations by Staropoli et al. on *Cln3<sup>Δex7-8</sup>* mice up to 16 months of age yielded similar results (Staropoli et al., 2012). However, they report virtual no change in a-wave response in 16 month old mice. It is possible a marked drop in the a-wave amplitude occurs between the 16th and 18th month. Similar ERG measurements were also reported in *Cln3*<sup>-/-</sup> mice (Katz et al., 2008).

In contrast, OKT thresholds and ERGs measurements of *Cln6<sup>ncl</sup>* mice showed a markedly early impaired retinal function. The ERGs indicated an early photoreceptor-dominated degeneration followed by inner retinal degeneration. Interestingly, ERG responses were already impaired at one month of age, whereas OKT threshold changes were only significant from five months of age onwards. Thus, there was a close concordance of early diminished ERG response with retinal thinning and quantitative cell loss. Of note, the phenomenon of discordant electrophysiological and visual behavioral profiles has been recently described in mutant rhodopsin transgenic rats (McGill et al., 2012). Similar to the present study, OKT threshold in rhodopsin transgenic rats did not decline until months after significant photoreceptor loss.

The ERG data obtained from *Cln6<sup>ncl</sup>* mice is again, similar of the phenotype described in *Cln8<sup>md</sup>* mice (Chang et al., 1994). The amplitudes of the a- and the b-wave rapidly declined with age and

the ERG was nearly undetectable at six months in *Cln8<sup>mnd</sup>* mice (Chang et al., 1994). The *Ppt1<sup>-/-</sup>* model shows mild reductions in both a- and b-wave at four months but has dramatic changes in ERGs at eight months (Lei et al., 2006). Overall, *Cln3<sup>Δex7-8</sup>* mice have the latest and mildest form of retinal degeneration when compared to other NCL models studied.

Comparative analysis of retinal degeneration in the NCL models is, however, confounded with the recent discovery of the *Crb1<sup>rd8</sup>* mutation in the C57BL/6N genetic background (Mattapallil et al., 2012). *Cln3<sup>Δex7-8</sup>* and relevant *Cln3<sup>+/+</sup>* mice were found to be positive for the *Crb1<sup>rd8</sup>* mutation, which explains why ERG response amplitudes decreased for *Cln3<sup>+/+</sup>* mice by one-third between 6 and 18 months. It also makes it difficult to assess how much of the *Cln3<sup>Δex7-8</sup>* retinal degeneration observed via OKT and ERGs is really due to the CLN3 mutation. Whether the *rd8* mutation influences CLN3 and to which extent is unknown. Furthermore, ERGs published by Staropoli et al. were also conducted on animals with a the C57BL/6N genetic background (Staropoli et al., 2012). Further studies on *Cln3<sup>Δex7-8</sup>* mice crossed onto another background, such as C57BL/6J, will elucidate the severity of retinal degeneration in these mice. On the other hand, *Cln6<sup>nclf</sup>*, *Cln8<sup>mnd</sup>*, *Ppt1<sup>-/-</sup>* and *Cln3<sup>-/-</sup>* mice mentioned in the above studies were done on mice with C57BL/6J background, where the *rd8* mutation has not been reported. Furthermore, the *Cln6<sup>nclf</sup>* mice used in this study all test negative for the mutation. It is safer to assume that retinal phenotypes reported in these mouse models is correct.

## 5.2 Microglia and Müller Cells in NCL Retinal Degeneration

There is a growing consensus that microglia and astrocytes contribute significantly or even trigger apoptosis in several diseases including retinal dystrophies (Schuetz and Thanos, 2004; Maragakis and Rothstein, 2006). Microglia and Müller cells are usually the first cells which respond to distress signals in the retinal and brain by altering morphology, up/down regulating protein and mRNA marker expression in addition to migrating to distressed sites. It is not surprising that activation of these cell types have been found in neurodegenerative diseases such as Alzheimer's, multiple sclerosis and Parkinson's (Boillee et al., 2006; Kim and Joh, 2006). Furthermore, brain studies on NCL animal models as well as patients have also revealed the presence of activated microglia cells and astrocytes, often in localized area where significant cell death occurs (Kohlschutter et al., 1993a; Thelen et al., 2012). However, the presence and contribution of glia cells in NCL retinal degeneration is unknown. The second part of this thesis aimed to characterize microglial and

Müller cell phenotype in the retina and study whether these cells cause and/or contribute to cell death.

### 5.2.1 Glial Activation in *Cln3<sup>Δex7-8</sup>* Retina

*Cln3<sup>Δex7-8</sup>* retinas showed up-regulated GFAP expression, a Müller cell marker, as early as six months of age. However, microglia morphology was comparable to wild type even at 12 months of age and active microglia were seen at 18 months. Since microglia respond to dysfunction of photoreceptors or changes in microenvironment, it is possible that these changes are too subtle for the microglia to pick up or there are sufficient signals from other cells blocking the microglial activation pathway. Since Müller cells span the entire retina and help regulate homeostasis, these cells would be more prone to detecting subtle changes in the retina environment. It is also possible that the pathways in the Müller cells themselves is affected by the *Cln3<sup>Δex7-8</sup>* mutation causing stress and impaired cell function. Intriguingly, Katz et al. only detected CLN3 protein expression in the mitochondria of Müller cells and inner retinal cells in wild type mice (Katz et al., 1997). This would also explain why the inner retinal cells of *Cln3<sup>Δex7-8</sup>* mice are more affected in the ERGs than photoreceptors. Similarly, low grade activation of astrocytes has also been reported in brains of both the *Cln3<sup>-/-</sup>* and *Cln3<sup>Δex7-8</sup>* mice with little macrophage morphology of microglia. Taken together, the *Cln3<sup>Δex7-8</sup>* retinal phenotype is most likely caused by stressed Müller cells and inner retinal cells due to dysfunctional mitochondria. It is also likely Müller cells are unable to maintain their regulatory functions at later stages in the CLN3 disease resulting in decreased maintenance of photoreceptors cells which in turn send out stress signals to the microglia.

The importance astrocytes play in NCL has also been demonstrated in the *Ppt1<sup>-/-</sup>* mice. Reactive astrocytes were attenuated in these mice by cross breeding with *GFAP<sup>-/-</sup> Vimentin<sup>-/-</sup>* mice resulting in an earlier and faster degenerative phenotype with profound neuroinflammatory response (Macauley et al., 2011). However, the up-regulation GFAP expression is normally the first pathological changes observed in the *Ppt1<sup>-/-</sup>* brains (Kielar et al., 2007; Macauley et al., 2009). The exact role these glial cells play in NCL pathology is not yet clear. It would be interesting to study if *Cln3<sup>Δex7-8</sup>* mice would also have an accelerated phenotype when astrocytes/Müller cells were attenuated. This may help elucidate if astrocytes play a more neuroprotective or deleterious role.

### 5.2.2 Glial Activation in *Cln6<sup>nclf</sup>* Retina

Müller cell analysis using GFAP staining and mRNA expression showed early activation already present in one month *Cln6<sup>nclf</sup>* mice which progressively increased with age. This is considerably earlier than GFAP staining of astrocytes in *Cln6<sup>nclf</sup>* cerebral cortices, which appear between five to six months of age (Bronson et al., 1998; Thelen et al., 2012). Therefore, gliosis associated with neuronal degeneration in the *Cln6<sup>nclf</sup>* mouse seems to occur in the eye before the brain. Iba1 detection of microglial cells in retinal sections and flat-mounts demonstrated a mixed population of alerted microglia at one month of age which became a homogenous group of amoeboid microglia by four months. Amoeboid microglia were seen migrating into nuclear and photoreceptor layers coinciding with a loss of microglial network. The presence of amoeboid microglia was followed by rapid decrease in OKT measurements, as well as accelerated thinning of the photoreceptor layer. This suggests that microglia actively contribute to accelerating retinal degeneration once fully active. The presence of active microglia before massive cell death has also been reported in the retinoschisis *Rs1h<sup>-</sup>/Y* mouse. In this model, microglia activating transcripts precede gene expression patterns related to apoptosis and microglial transformation from ramified to an amoeboid phagocytic morphology coincided with cell death (Gehrig et al., 2007; Ebert et al., 2009). Furthermore, highly activated microglia which transformed to a phagocytic shape was seen past one year of age in the *Cln6<sup>nclf</sup>* mouse brain (Thelen et al., 2012). Similar to induction of reactive astrocytes, microglia activation occurs much later in the brain compared to retina.

Alerted microglial cells also contained auto-fluorescent granules at all ages examined, which could reflect phagocytic processes of dying neurons affected by lysosomal storage of ceroid lipofuscin. In *Ppt1<sup>-/-</sup>* mice, F4/80 stained mostly microglia in brain regions with prominent neuro-pathological changes (Bible et al., 2004). However, storage body accumulation was evenly spread in the brain, indicating that lipofuscin deposits per se may not be the trigger for microglial activation (Bible et al., 2004). Conversely, in the *Cln6<sup>nclf</sup>* brain, widespread microglial activation closely resembling that of lipopigment storage was seen along with localized clusters of activated microglia and astrocytes (Thelen et al., 2012). This data suggests that lipofuscin may trigger activation of microglia cells, however the presence of localized clusters indicate that other signals are also present. These signals may come from stressed neurons and astrocytes/Müller cells.

A deeper analysis of inflammation and glial cell activation in the *Cln6<sup>nclf</sup>* mouse retina was done via temporal mRNA expression profiling. TUNEL assays of *Cln6<sup>nclf</sup>* retinas revealed the constant presence of apoptosis which is also seen with apoptosis transcript marker CD95. However, highest CD95 expression was seen at one and six months, which is also when TUNEL assays were done. At other ages, CD95 expression is higher than wild type, but not significantly, indicating the presence of constant low level apoptosis. It is likely the number of TUNEL stained cells would have also been lower at other ages tested. Inflammatory marker expression, TNF $\alpha$ , was also increased in *Cln6<sup>nclf</sup>* mice at all ages, but never significantly, indicating the presence of low-grade inflammation.

Strong and early induction of EDN2 and C1qa were also present in *Cln6<sup>nclf</sup>* retinas. EDN2 was initially described as a secreted factor of stressed photoreceptors that binds to its receptor EDNRB on Müller cells (Rattner and Nathans, 2005). In turn, Müller cells produce leukemia inhibitory factor, which triggers release of the survival factor FGF2 in Müller cells and/or photoreceptors to protect neurons from further damage (Joly et al., 2008). However, studies on glaucomatous DBA/2J show EDN2 is very early up-regulated in retinal microglia and blocking EDN2 with antagonist bosentan reduced the incidence of glaucoma development in these mice (Howell et al., 2011). The authors speculate since EDN2 is a potent vasoactive peptide, it induces vasoconstriction in the ONH and retina during glaucoma causing degeneration. It is unclear whether EDN2 in the *Cln6<sup>nclf</sup>* retina is neuroprotective or a microglia-specific signal that triggers photoreceptor degeneration. A very similar temporal expression profile was also detected for C1qa. C1qa is subunit of the macromolecular C1q complex exclusively synthesized by monocytes, macrophages, and microglial cells (Muller et al., 1978; Schafer et al., 2000). As part of the classical complement activation pathway, C1qa is a reliable marker of pro-inflammatory non-ramified microglial cells (Farber et al., 2009). The high expression of C1qa in *Cln6<sup>nclf</sup>* retinas at all analyzed time points could suggest that alerted microglial cells are present at the very initial stages of NCL disease progression. Since C1qa triggers pro-inflammatory cytokine release, phagocytosis and oxidative burst in an autocrine and paracrine way (Farber et al., 2009), a constant high level of C1qa in *Cln6<sup>nclf</sup>* retinas may reflect chronic inflammatory events in NCL.

Activated phagocytic microglia marker CD68 was strongly increased at one and six month in *Cln6<sup>nclf</sup>* retinas with increased expression at other ages. This expression profile is similar to that of CD95, suggesting a co-incident of increase phagocytosis and apoptosis. EGR1 transcript levels were also strongly increased in *Cln6<sup>nclf</sup>* retinas from four months onwards, with increased expression

from one to three months. EGR1 up-regulation is commonly associated with microglial activation and their migration into the nuclear layers (Langmann, 2007b; Langmann et al., 2009). Interestingly, in the retinal degeneration slow (*rds*) mouse, the EGR1 response was accompanied by induction of neurotrophic factors (Sharma et al., 2012). These authors therefore hypothesized that activation of EGR1 and neurotrophic factors could represent a protective immune mechanism contributing to the characteristically slow retinal degeneration of *rds* mice (Sharma et al., 2012). The exact function of EGR1 in *Cln6<sup>nc1f</sup>* microglial cells is unknown and needs further exploration.

Overall, *Cln6<sup>nc1f</sup>* retinas have an early induction of glial and inflammatory response which coincides with accelerated cell death. However, whether microglial activation is the main cause of cell death is unclear. Since morphometric and ERG analysis show retinal degeneration already occurs in one month old *Cln6<sup>nc1f</sup>* mice, and no studies have been done prior that that age, it is difficult to assess if the retinas of these mice simply never fully develop, or if cell death is occurring independent or dependent on microglial activation. Studies on CLN6 sheep have shown activated glial cells present in embryo 40 days before animals were born (Oswald et al., 2005). It is possible that enough microglia cell are active before the one month time point to cause significant degeneration to the retina and that this activation only gets worse as the mice age.

### 5.3 Immuno-modulation and Neuronal Degeneration Rescue via Dietary Supplements

With the increasing evidence that activated microglial cells release neurotoxic molecules including pro-inflammatory cytokines and reactive oxygen species which contribute to neurodegenerative processes, heightened effort are being made in finding neuroinflammation-targeting therapeutics. This includes screening approved CNS drugs, developing novel synthetic compounds which selectively down-regulate neuroinflammation and isolating active compounds from natural products (Choi et al., 2011). In fact, several natural compounds exist which can target microglial pathways whilst supporting neuronal survival. Curcumin is a herbal medicine which has been used for centuries in India and China (Ammon and Wahl, 1991). Curcumin has been shown to reduce toxic microglial secretions and protect neurons and photoreceptors (Jin et al., 2007; Jung et al., 2006; He et al., 2010; Mandal et al., 2009). Luteolin, a flavonoid abundant in leafy greens (Lopez-Lazaro 2009), has been shown to reduce microglia reactivity *in vivo* and induce neuroprotective phenotype *in vitro* (Jang et al., 2008; Dirscherl et al., 2012). DHA is highly enriched in the retina

and is a precursor for neuroprotectin D1, promoting the survival of photoreceptors and RPE cells (Mukherjee et al., 2007). It has also been shown to inhibit microglial synthesis of pro-inflammatory cytokines (Antonietta Ajmone-Cat et al., 2012). Furthermore, reports on patients with juvenile NCL have found reduced DHA levels in the plasma and cerebral cortex, which may contribute to retinal and brain degeneration (Kohlschutter et al., 1993b). On the same note, other hereditary forms of retinal degeneration have also been described to have low DHA levels and have used dietary supplementation as a therapeutic option (Schaefer et al., 1995; Ebert et al., 2009).

Targeting the immune system in NCL is not a novel idea. Studies done by Groh et al, in which lymphocytes were inactivated in *Ppt1*<sup>-/-</sup> mice, showed substantial disease attenuation (Groh et al., 2013). Pharmacological and genetic suppression of the immune system in the *Cln3*<sup>-/-</sup> mouse resulted in improved motor performance (Seehafer et al., 2011). Since reactive microglia have also been identified in CLN3 patients (Haltia, 2003), targeting the immune system and by extension, inflammation, has now become an option for therapeutic intervention. The third part of this thesis was to select the NCL mouse model with the most prominent glial activation and supplement these mice with anti-inflammatory diets in order to reduce glial reactivity and promote neuronal survival. As the *Cln6*<sup>nclf</sup> mice were found have early Müller and microglial induction which correlates with cell death, mice were supplemented with 0.6% curcumin, 0.6% luteolin or 5% DHA for thirty weeks directly after weaning.

With all three dietary regimens, OKT measurements were significantly higher compared to non-supplemented control mice starting at three months for curcumin and DHA and five months for luteolin-supplemented mice. Luteolin-supplemented mice had uneven OKT measurements which showed initial improvement at three months but drastic decrease in thresholds at four months and improvement again thereafter. This puzzling "roller-coaster" effect may be due to an infection these particular mice got during the experiment or potential toxic effects of the compound. However, no verifications were made. ERG analysis also showed improvements in b-wave for all three regimens with DHA having the greatest preservation of the a-wave. The preservation of the photoreceptor layer and particularly the outer segments in DHA-treated mice was also highlighted in morphometric and histological analyses. A beneficial effect on photoreceptor outer segments has also been seen in DHA supplementation of rhodopsin mutant rats, although no alteration in the rate of retinal degeneration was detected (Martin et al., 2004). Surprisingly, curcumin did not have a larger effect on retinal preservation. Previous studies on rats with light induce retinal

degeneration which were supplemented with 0.2% curcumin diet were able to show significant decrease in ONL degeneration (Mandal et al., 2009). However, the improvement in ERG measurements of these curcumin-supplemented rats is similar to that of the curcumin-supplemented *Cln6<sup>nclf</sup>* mice. Moreover, mice with type 2 diabetes which were given a 2% DHA diet also had similar improvements in retinal function as DHA-supplemented *Cln6<sup>nclf</sup>* mice (Sapieha et al., 2012).

Immunohistochemical analysis of microglia with Iba1 showed mainly ramified cells in all supplemented *Cln6<sup>nclf</sup>* retinas compared to the amoeboid microglia in controls. However, cross sections did show amoeboid microglia migrated into cells layers. Nevertheless, these amoeboid microglia did retain extended ramifications, which was not seen in the controls. With these somewhat contradictory results, it is important to note that microglia morphology is not always equivalent to inflammation state (Graeber et al., 2011). The microglia morphology identified in the supplemented *Cln6<sup>nclf</sup>* retinas look similar to those found in DHA-supplemented retinoschisis-deficient mice (Ebert et al., 2009). In this retinal degeneration model, the ramified microglial population produced less pro-inflammatory cytokines and the retinal morphology was improved upon DHA-treatment (Ebert et al., 2009). Furthermore, BV2 microglia cells treated with LPS (lipopolysaccharide) and luteolin also had somewhat amoeboid microglia with long ramified protrusions (Dirscherl et al., 2010). These *in vitro* studies also showed that luteolin was able alter microglia transcriptom making it a potent modulator of microglial activation by inducing an anti-inflammatory, anti-oxidative, neuroprotective phenotype. With this in mind, it is tempting to speculate that DHA- and in part curcumin and luteolin-supplemented *Cln6<sup>nclf</sup>* retinas display less microglial reactivity. Accumulation of lipofuscin deposits for control and supplemented retinas appeared to be similar in all cases.

Both luteolin and curcumin did not significantly alter mRNA expression of inflammatory or microglial markers. This is quite surprising since *in vivo* studies of mice supplemented with luteolin and curcumin have shown decreased expression of pro-inflammatory cytokines such as IL-6 and IL-1 $\beta$  (Jang et al., 2008; He et al., 2010). Furthermore, *in vitro* studies done with both compounds on LPS-activated BV2 cells induced the expression of distinct anti-inflammatory gene clusters (Dirscherl et al., 2010; Karlstetter et al., 2011).

DHA-supplementation also had surprising effects on the retinal mRNA marker expression. Along with the expected decrease in apoptosis and inflammatory marker expression of caspase 8 and CD95, retinas had an unexpected up-regulation of "classical" activated microglia markers: C1qa, CD68 and EGR1 (data not shown). In addition, these eyes also had decreased expression of Tgfb $\beta$ , a marker for 'alternatively' activated microglia associated with neuroprotection. These data suggest that DHA-supplementation in *Cln6<sup>nclf</sup>* mice pushes for a more activate microglial phenotype, however morphology studies suggest the microglia are not completely active. This expression profile is in contrast to other studies done concerning microglia and DHA, which report a decrease in similar markers (Ebert et al., 2009). Furthermore, studies done on DHA-supplemented type 2 diabetes mice, showed no change in expression of similar markers, despite improvement in retinal function (Sapieha et al., 2012). It is possible that DHA supplementation in *CLN6<sup>nclf</sup>* retina push microglia to better clear debris and dead cells without letting microglia reach fully alerted states. This would also explain how apoptosis markers are significantly decreased in these retinas. Decrease in apoptosis can also be attributed to preservation of the photoreceptor outer membranes (German et al., 2006). Although, DHA levels in the *Cln6<sup>nclf</sup>* mouse have not been verified. it is likely these mice, similar to JNCL patients, have low concentrations of DHA in neural tissues (Kohlschutter et al., 1993b).

Nonetheless, these studies are not without limitations. Luteolin and curcumin supplementation were expected to yield better preservation of the *Cln6<sup>nclf</sup>* retina. As both substances are hormetic (Mattson and Cheng, 2006; Son et al., 2008), and no previous study has supplemented mice for the length of this study, it is possible that curcumin and luteolin had some toxic effects. Furthermore, curcumin supplementation studies done on Neimann-Pick disease type C (NPC) mice did lead to toxic effects as these mice have innate low levels of cytochrome P450, an important enzyme which catalyzes the metabolism of organic products and drugs (this work is not yet published and is in review). Curcumin has also been shown to decrease cytochrome P450 levels in rat liver (Oetari et al., 1996). This combined effect led to toxic build up of curcumin in NPC mice. Cytochrome P450 levels have not verified in NCL patients or mice, but since both NPC and NCL are neurodegenerative lysosomal storage diseases, it may be an explanation as to why curcumin supplementation did not yield better results. Supplementation studies would have to be tested on wild type mice and new studies would have to be done with lower doses.

mRNA marker expression data may have also been influenced by the low number of mice dedicated to those experiment (n=5). Since NCL is an individual disease, it is also expected that treatment would have individual results. A larger number of mice would have compensated for this variability. Finally, the amount of dietary substance which was reabsorbed and cross the blood brain/retinal barrier is unknown. There is evidence that flavonoids Naringenin and Quercetin are able to penetrate into the brain (Youdim et al., 2004) but this has not been determined for luteolin. Furthermore, curcumin has been detected in the forebrain of mice after systemic injection (Purkayastha et al., 2009) and bioactive levels have been shown in the retina after dietary supplementation, however curcumin accumulation has not been experimental proven in the retina (Mandal et al., 2009). DHA accumulation in the retina has been reported in the rod outer segment in mice supplemented with flaxseed oil (Martin et al., 2004). On the other hand, the effect these supplements had on the retina could be seen by the positive results in ERG and OKT measurements implying that these supplements did have some influence on visual function.

## 5.4 Perspective

### 5.4.1 Cln3 and Cln6: Different but Similar?

Comparison of retinal degeneration of *Cln3<sup>Δex7-8</sup>* and *Cln6<sup>nclf</sup>* were confounded by the presence of the *Crb1<sup>rd8</sup>* mutation. Nonetheless, this raises the question of how dis/similar CLN3 and CLN6 are to each other, and how similarities and difference might be helpful in better understand NCL. Although, the CLN6 protein is localized on the ER membrane and CLN3 protein on lysosomal membrane, both have been implicated in autophagy mechanisms (Cao et al., 2006; Thelen et al., 2012). The *nclf* mutation in CLN6 has been suggested to inhibit fusion between autophagosomes and lysosomes whereas the 1-kb mutation in CLN3 delays the maturation of autophagic vacuoles (Cao et al., 2006; Thelen et al., 2012). Moreover, studies undertaken by Cao et al. compared gene expression via microarray of primary cerebellar neuronal precursor cells from *Cln6<sup>nclf</sup>* and *Cln3<sup>Δex7-8</sup>* mice revealed 36 shared probes (out of 1,662 total probes found to be different from wild type) with only 8 concordant in their direction of change (Cao et al., 2011). These experiments, as well as the ones done in this current study, reveal distinct patho-mechanism exist at least between CLN3 and CLN6 disease. This suggests that perhaps treatments which may work for one disease would not be so effective in the other. However, better understanding of one of these proteins would help elucidate what the function of other NCL proteins may be. Also, the protein expression

pattern of CLN6 and most of the other NCLs (such as in Müller cells or certain neurons) would also help elucidate which cell types are more affected by the mutation.

Finally, studies in this thesis have shown that the ocular phenotype in NCL is helpful to understand molecular mechanisms and could also be useful to develop diagnostic tools for experimental therapies. Since vision loss is relatively easier to quantify than motor and behavioral deterioration in NCL mouse models, preclinical therapies which ameliorate the retinal phenotype could be an effective means to monitor effects on the brain. However, this could only apply to mouse model which exhibit a retinal phenotype.

### **5.4.2 Müller Cells, Microglia and Modulation via Natural Compounds**

In both *Cln3<sup>Δex7-8</sup>* and *Cln6<sup>ncf</sup>* retina, Müller cells were found to be reactive. Whether this is because of dysfunctional mitochondria, photoreceptor cell death, both or other mechanisms remains to be elucidated. Similarly, the balance between neuroprotective and neurodegenerative microglia as well as their role in *Cln6<sup>ncf</sup>* retinas needs to be further explored. From these studies, the blurred lines between what defines "classically" and "alternatively" activated microglia make it difficult to assess how much damage microglia cause. This study also highlights the importance of comparing microglia morphology and marker expression to get a better understanding of microglial reactivity.

As a final point, there is a lot of promise for using natural immuno-modulating compounds as a treatment option of neurodegenerative disease. As the knowledge of microglial behavior and function in the retina and brain increases, microglia themselves have become a target for therapeutic intervention. Clinical trials studying the positive effect of curcumin on Alzheimer's disease are underway ([clinicaltrials.gov](http://clinicaltrials.gov)). Furthermore, curcumin is also being used as a non-invasive biomarker for detecting  $\beta$ -amyloid plaques in the eyes of AD patients via retinal imaging. Beneficial effects of resveratrol, *ginseng* and green tea, amongst a growing number of compounds, have all been shown to have positive effects in disease and reduce microglia activating pathways (Choi et al., 2011).

Unfortunately there is no widely accepted treatment that can cure, slow down, or stop the symptoms of NCL, although phase I clinical trial of neural stem cells for INCL and

---

immunosuppressants for JNCL can slow disease progression for a limited time (clinicaltrials.gov; <http://www.bdsra.org/research/Pearce-trial.htm>). There is still a lot of work which needs to be done in the NCL field towards understanding CLN protein mechanisms, all the key players in NCL pathology, and treatment development. Based on the studies done in this thesis, increase in dietary anti-inflammatory compounds starting at an early enough time point would help reduce inflammation and slow disease progression. However, this type of intervention is by no means a cure and would be most beneficial if paired with another treatment option.

## 6. Summary

Microglia are specialized macrophages of the central nervous system involved in immune regulation, tissue development, homeostasis and wound repair. In healthy tissue, microglia are found in a ramified state which is tightly controlled by neurons. Upon insult, microglia undergo morphological changes, resembling active phagocytic macrophages and are highly motile. In neurodegenerative diseases, such as Alzheimer's or multiple sclerosis and in most inherited retinal dystrophies, microglia cells are found in a permanent pro-inflammatory active state which exacerbates cell death and disease progression. Similarly, astrocytes in the brain or Müller cells in the retina, also become reactive in diseased tissue and may contribute to disease progression through overshoot release of protective factors such as VEGF (vascular endothelial growth factor), massive proliferation and release of inflammatory intermediates which recruit microglia to site of injury. Along with active microglia, reactive astrocytes/Müller cells are also found in virtually all neurodegenerative and retinal dystrophies.

Microglia and Müller cell status has not been well defined in retinal degeneration of neurodegenerative disease neuronal ceroid lipofuscinosis (NCL). The NCLs are early onset lysosomal storage disorders characterized by vision loss, mental and motor deficits, and spontaneous seizures. Massive accumulation of auto-fluorescent material in neurons lead to progressive neuronal degeneration and cell death. Furthermore, neuropathological analyses of autopsy material from NCL patients and animal models revealed brain atrophy closely associated with microglial and astrocyte activity. However, it is unclear whether this phenomenon is mainly confined to the brain or also occurs in the retina.

Two mouse models of NCL, *Cln3<sup>Δex7-8</sup>* and *Cln6<sup>nclf</sup>*, were selected for detailed characterization of retinal degeneration with focus on microglia and Müller cell activity. Studies showed that *Cln3<sup>Δex7-8</sup>* mice had a late onset of retinal degeneration which started at 9 months and progressed until severe retinal impairment at 18 months. Reactive Müller cells were present starting at six months with no significant microglial activation until late disease stage. Furthermore, degeneration originated from inner retinal cells as seen through electroretinograms with little photoreceptor death. In contrast, temporal studies on *Cln6<sup>nclf</sup>* mice showed an early progressive retinal degenerative phenotype which started before one month of age resulting in loss of vision and

retinal function by eight months. Full retinal degeneration was accompanied by reactive Müller cells already present at one month of age and fully active microglia at four months. Mixed population of ramified and active microglia were seen at one month. Transcript profiling of the *Cln6<sup>ncl</sup>* mouse retina also showed up-regulated expression of apoptotic, inflammatory and active microglia markers.

Based on the strong reactivity of microglia, *Cln6<sup>ncl</sup>* mice were supplemented with immunomodulatory compounds curcumin, luteolin or DHA in order to ameliorate microgliosis and reduce retinal degeneration. Studies showed *Cln6<sup>ncl</sup>* mice supplemented with 0.6% curcumin, 0.6% luteolin or 5% DHA had improved retinal function, better visual acuity and DHA-supplementation had the greatest preservation of photoreceptors. All supplements were able to attenuate microglia activation as seen by the presence of microglial ramification and intact network. However, curcumin and luteolin supplementation did not have any effect on retinal transcriptome whilst DHA-supplementation reduced expression of inflammatory and apoptotic markers.

Taken together, microglial reactivity accompanies disease progression in the *Cln6<sup>ncl</sup>* retina but not *Cln3<sup>Δex7-8</sup>*. Immuno-modulating compounds were able to attenuate disease progression and reactive microglia to a certain extent in *Cln6<sup>ncl</sup>* mice, indicating modulation of microglial activity could be helpful in preserving vision and may ameliorate neuronal degeneration in NCL. Finally, inspection of the retinal function may also allow to monitor general disease progression and could be used to assess the efficacy of therapeutic interventions for NCL patients.

## 7. Zusammenfassung

Mikrogliazellen sind spezialisierte Makrophagen des zentralen Nervensystems, die an der Immunoregulation, Gewebeentwicklung und Wundheilung beteiligt sind. Im gesunden Gewebe liegen Mikrogliazellen in einer verzweigten Form vor, welche von Neuronen kontrolliert wird. Nach einer Schädigung ändert sich die Morphologie der Mikrogliazellen und ähnelt dann der von aktivierten, phagozytischen Makrophagen. Außerdem werden die Mikroglia dadurch sehr beweglich. In neurodegenerativen Erkrankungen, wie Alzheimer oder multiple Sklerose, und in den meisten erblichen Netzhautdystrophien befinden sich Mikrogliazellen dauerhaft in diesem proinflammatorischen Zustand, welcher den Zelltod und die Progression der Erkrankung beschleunigt. In ähnlicher Weise werden Astrozyten im Gehirn oder Müllerzellen in der Netzhaut im erkrankten Gewebe aktiviert und können den weiteren Verlauf der Erkrankung negativ beeinflussen. Neben aktiven Mikrogliazellen kommen auch reaktive Astrozyten/Müllerzellen in praktisch allen neurodegenerativen und retinalen Dystrophien vor.

Die neuronalen Ceroid-Lipofuszinosen (NCL) sind neurodegenerative Erkrankungen, welche mit einer Netzhautdegeneration einhergehen. Hier ist der Einfluss von Mikroglia und Müllerzellen noch nicht genau bekannt. Die NCL-Erkrankungen sind lysosomale Speicherkrankheiten, die im frühen Lebensalter beginnen und durch Sehverlust, mentale und motorische Defizite und spontane epileptische Anfälle charakterisiert sind. Eine massive Anreicherung von autofluoreszentem Material in den Nervenzellen führt zu fortschreitender Neurodegeneration und zum Zelluntgang. Außerdem zeigen neuropathologische Untersuchungen an Autopsiematerial von NCL-Patienten und an Tiermodellen eine Hirnatrophie, die eng mit der Aktivität der Mikroglia und Astrozyten assoziiert ist. Es bleibt jedoch unklar, ob sich dieses Phänomen nur im Gehirn abspielt, oder ob es auch in der Netzhaut auftritt.

Zwei Mausmodelle für NCL, *Cln3<sup>Δex7-8</sup>* und *Cln6<sup>nclfb</sup>*, wurden für eine detaillierte Charakterisierung der Netzhautdegeneration untersucht, wobei der Fokus auf die Aktivität der Mikroglia und der Müllerzellen gelegt wurde. Studien haben gezeigt, dass die Netzhautdegeneration bei *Cln3<sup>Δex7-8</sup>*-Mäusen erst spät einsetzt. Diese beginnt im neunten Lebensmonat und wird bis zum achtzehnten Lebensmonat progressiv schlechter. Das Endstadium der Erkrankung ist schließlich durch eine schwere Netzhautschädigung gekennzeichnet. Reaktive Müllerzellen konnten ab dem sechsten

Monate identifiziert werden. Eine Aktivierung von Mikrogliazellen hingegen wurde erst in einem späten Stadium der Krankheit beobachtet. Des Weiteren begann die Degeneration in den inneren Netzhautschichten, wie durch Elektroretinogramme gezeigt werden konnte, wobei die Photorezeptoren kaum von dem Zellsterben betroffen waren. Im Gegensatz dazu zeigten Studien an *Cln6<sup>ncl</sup>*-Mäusen einen frühzeitigen, progressiv degenerativen Phänotyp der Retina, welcher vor dem ersten Lebensmonat begann und zum Verlust der Sehkraft und der Netzhautfunktion im achten Lebensmonat führte. Während des gesamten Prozesses konnten reaktive Müllerzellen beobachtet werden, welche schon im ersten Lebensmonat auftraten. Ferner wurden im ersten Monat gemischte Gruppen von verzweigten und aktivierten Mikroglia identifiziert, welche alle nach vier Monaten komplett aktiv waren. Expressionsprofile der Netzhaut von *Cln6<sup>ncl</sup>*-Mäusen zeigten zudem eine erhöhte Expression von apoptotischen, inflammatorischen und aktiven Mikroglia markern.

Aufgrund der starken Aktivierung der Mikrogliazellen wurden *Cln6<sup>ncl</sup>*-Mäuse mit den immunmodulatorischen Substanzen Curcumin, Luteolin oder DHA behandelt. Ziel war es, die Mikrogliose zu verbessern und die Netzhautdegeneration zu mildern. Studien zeigten, dass 0,6% Curcumin, 0,6% Luteolin oder 5% DHA zu einer verbesserten Netzhautfunktion und einer besseren Sehschärfe führten. Ferner wurde bei Behandlung mit DHA der größte Erhalt von Photorezeptoren beobachtet. Alle Substanzen konnten die Aktivierung der Mikroglia abmildern, was durch die Anwesenheit von verzweigten Mikroglia in einem intakten Netzwerk belegt werden konnte. Jedoch hatten Curcumin und Luteolin keine Wirkung auf das retinale Expressionsprofil, während DHA die Expression von inflammatorischen und apoptotischen Marker reduzierte, aber auch und die Expression der Mikroglia marker hochregulierte.

Zusammenfassend kann gesagt werden, dass der Phänotyp von *Cln6<sup>ncl</sup>*-Mäusen mit einer Aktivierung von Mikroglia einhergeht. Diese konnte jedoch nicht bei *Cln3<sup>Δex7-8</sup>*-Mäusen beobachtet werden. Immunmodulatorische Substanzen waren bei *Cln6<sup>ncl</sup>*-Mäusen innerhalb eines gewissen Rahmens in der Lage, das Fortschreiten der Erkrankung abzumildern und die Aktivierung der Mikroglia einzugrenzen. Dies deutet darauf hin, dass sich die Beeinflussung der Mikrogliaaktivität positiv auf den Erhalt der Sehkraft auswirkt und dass die Neurodegeneration bei NCL-Patienten abgeschwächt werden kann. Schlussendlich kann die Überprüfung der Netzhautfunktion auch dazu dienen, den Fortschritt der Erkrankung zu überwachen und die Wirkung einer Therapie für NCL-Patienten zu beurteilen.

---

## List of Abbreviations

AAP	Antartctic Phophatase
abcr <sup>-/-</sup>	ATP-binding cassette, sub-family A (ABC1), member 4 knock out mouse
AD	Alzheimer's disease
ALS	amyotrophic lateral sclerosis
AMD	Age-related Macular Degeneration
ANCL	Adult neuronal ceroid lipofuscinosis
ATP	Adenosine-5'-triphosphate
ATP13A2	ATPase type 13A2
ATPase	Adenosintriphosphat Synthase
B.D.	Big Dye
bp	Base pairs
BSA	Bovine serum albumin
c	Concentration
c/d	Cycles per degree
C1qa	Complement C1q subunit a
Casp8	Caspase 8
CD11b	CD11b ligand
CD18	CD18 ligand
CD200	CD200 ligand
CD200R	CD200 receptor
Cd68	CD68 antigen
Cd95	CD95 antigen
cDNA	copy DNA
cDNA	Complementary DNA
CLN	Ceroid lipofuscinosis
<i>Cln3</i> <sup>-/-</sup>	<i>Cln3</i> knock out mouse
<i>Cln3</i> <sup>+/+</sup>	<i>Cln3</i> wild type mouse
<i>Cln3</i> <sup><math>\Delta</math>ex7/8</sup>	<i>Cln3</i> exon 7-8 knock-in mouse
<i>Cln6</i> <sup>+/+</sup>	<i>Cln6</i> wild type mouse
<i>Cln6</i> <sup><i>nclf</i></sup>	<i>Cln6 nclf</i> mouse

---

CLN6p	CLN6 protein
CNS	Central nervous system
CO <sub>2</sub>	Carbon dioxide
CRB1	Crumbs homolog 1
CRB1 <sup>rd8</sup>	Rd8 mutation in CRB1 gene mouse model
CRMP-2	collapsin response mediator protein-2
CSP $\alpha$	Cysteine-string protein alpha
CT	Cycle Threshold
CTSD	Cathepsin D
CTSF	Cathepsin F
CX3CL1	chemokine (C-X3-C motif) ligand 1
CX3CR1	chemokine (C-X3-C motif) receptor 1
d	thickness
DAB	3,3'-Diaminobenzidine
DAPI	4',6-Diamidino-2-phenylindol
DHA	Docosahexaenoic acid
DNA	Deoxyribonucleic Acid
DNAJ	DNAJ chaperone
DNAJC5	DnaJ homolog subfamily C member 5
DNAse	deoxyribonuclease
dNTPs	Deoxynucleotide Triphosphates
dUTP	2'-Deoxyuridine, 5'-Triphosphate
E	extinction
EDN2	Endothelin 2
EDTA	Ethylenediaminetetraacetic acid
EEG	Electroencephalogram
EGR1	Early growth response 1
ER	Endoplasmic reticulum
ERG	Electroretinogram
EtOH	Ethanol
Exol	Exonuclease
F4/80	surface glycoprotein F4/80
FRET	Fluorescence resonance energy transfer

GCL	Ganglion cell layer
gDNA	Genomic DNA
GFAP	glial fibrillary acidic protein
H <sub>2</sub> O	Water
H <sub>2</sub> O <sub>2</sub>	Hydrogen peroxide
HCl	Hydrogen chloride
HE	Hematoxylin-Eosin
Iba1	<i>ionized calcium binding adaptor molecule 1</i>
IFN $\gamma$	interferon- $\gamma$
IgG	Immunoglobulin G
IL1	Interleukin 1
IL-10	interleukin-10
IL-1 $\beta$	Interleukin -1 $\beta$
IL6	Interleukin 6
INCL	Infantile neuronal ceroid lipofuscinosis
INL	Inner nuclear layer
IPL	Inner plexiform layer
IS	Inner segment
JNCL	Juvenile neuronal ceroid lipofuscinosis
kb	Kilo base
KCTD7	Potassium channel tetramerization domain-containing protein 7
LED	Light-emitting diode
Lipo	Lipofuscin
LPS	Lipopolysaccharide
LSD	lysosomal storage disorder
MCP	Monocyte chemoattractant protein
M-CSF	Macrophage colony stimulating factor
MFSD8	Major facilitator superfamily domain containing 8
MgCl	Magnesium Chloride
MHC	Major histocompatibility markers
mnd	Motor neuro degeneration
mRNA	Messenger RNA
n.d.	Not determined

---

Na <sub>2</sub> HPO <sub>4</sub>	Sodium hydrogen phosphate
NaAC	Sodium Acetate
NaCl	Sodium Chloride
NaN <sub>3</sub>	Sodium Azide
NaOH	Sodium hydroxide
NCL	Neuronal ceroid lipofuscinosis
NFκB	nuclear factor kappa B
NPC	Neimann-Pick disease type C
O.C.T	optimum cutting temperature
OKT	Optokinetic tracking
OMIM	<i>Online Mendelian Inheritance in Men</i>
ON	Over night
ONL	Outer nuclear layer
OPL	Outer plexiform layer
OS	Outer segment
p	P value
PAMPs	pathogen-associated molecular patterns
PBS	Phosphate buffered saline
PCR	Polymerase chain reaction
PFA	paraformaldehyde
POD	Peroxidase
PPT1	Palmitoyl protein thioesterase 1
<i>Ppt1</i> <sup>-/-</sup>	Ppt1 knock out mouse
PR	Photoreceptor
PUFA	polyunsaturated fatty acid
qRT-PCR	quantitative real time RT-PCR
rd	retinal degeneration 1
rds	retinal degeneration slow
Retnet	Retinal Information Network
RNA	Ribonucleic Acid
RP	Retinitis Pigmentosa
RPE	Retinal pigment epithelium
rpm	Rotation per minute

Rs1h-/Y	Retinoschisis-deficient mouse
RT	Reverse transcription
RT	Room temperature
RT-PCR	Reverse transcription polymerase chain reaction
SD	standard deviation
SDS	Sodium dodecyl sulfate
SEM	Standard error of mean
SEP	Somatosensory evoked potential
Taq	Thermus aquaticus
TBE	TRIS-Borat-EDTA
TdT	terminal transferase
TGF $\beta$	Transforming growth factor beta
TNF	tumor necrosis factor
TNFR	tumor necrosis factor-R
TNF $\alpha$	Tumor necrosis factor $\alpha$
TPP1	Tripeptidyl peptidase 1
Tris	Tris(hydroxymethyl)-aminomethan
TUNEL	terminal deoxynucleotidyl transferase dUTP nick end labelling
UPL	Universal Probe Library
VEGF	vascular endothelial growth factor
VEP	Visual evoked potential
vLINCL	Variant late neuronal ceroid lipofuscinosis
w/v	Weight by volume
WT	Wild type
$\epsilon$	Extinction factor

## Conferences

2010

Annual Meeting of the European Macrophage and Dendritic Cell Society (EMDS)

Edinburgh, UK (Attendee)

2011

22nd Meeting of the German Society of Human Genetics

Regensburg, Germany

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster)

Pro Retina Research-Colloquium

Potsdam, Germany

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster)

1st JNCL PhD Symposium

Hamburg, Germany

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Speaker)

10th European meeting on Glial Cells in Health and Disease

Prague, Czech Republic

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster)

2012

13th International Congress on The Neuronal Ceroid Lipofuscinoses (Batten Disease)

London, England

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster, Poster awardee)

The Association for Research in Vision and Ophthalmology (ARVO) 2012

Fort-Lauderdale, USA

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster)

XX Biennial Meeting of the International Society of Eye research (ISER)

Berlin, Germany

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Poster, Novartis Travel Grant)

Jahrestreffen der NCL-Gruppe Deutschland

Barsinghausen, Germany

*Retinal degeneration and microglial activation in mouse models of neuronal ceroid lipofuscinosis*  
(Speaker)

2013

2nd JNCL PhD Symposium together with the Brains 4 Brains workshop

Frankfurt, Germany

*Curcumin, Luteolin and DHA Supplementation Abates Microglia Activation and Retinal Degeneration in the CLN6<sup>nclf</sup> Neuronal Ceroid Lipofuscinosis Mouse Model* (Speaker)

39th Annual Meeting of the Society of Neuropaediatrics

Innsbruck, Austria

*Retinal degeneration and Inflammation in neuronal ceroid lipofuscinosis (NCL)* (Speaker)

The Association for Research in Vision and Ophthalmology (ARVO) 2013

Seattle, USA

*Curcumin, Luteolin and DHA Supplementation Abates Microglia Activation and Retinal Degeneration in the CLN6<sup>nclf</sup> Neuronal Ceroid Lipofuscinosis Mouse Model* (Poster)

## Curriculum Vitae

**Myriam Mirza, M.Sc.**

**August 20, 1985, Montreal, Canada**

### Education

**Diploma of Collegial Studies, International Baccalaureate Program in Health Sciences.**

Champlain College, St-Lambert, CANADA. August 2002-June 2004

**Bachelor of Science: Honors Biochemistry.** McGill University, Montreal CANADA. August 2004 - June 2007.

**Master of Science: Biochemistry and Chemical Biology.** McGill University, Montreal CANADA. August 2007 - June 2009. Title: Characterization of New CFTR Monoclonal Antibodies

**Doctor of Philosophy in Science: Biology, Human Genetics.** Regensburg University, Regensburg, GERMANY. May 2010 – present. Title: Characterization of the retinal degeneration and glial activation of neuronal ceroid lipofuscinosis mouse models *Cln3* <sup>$\Delta$ ex7-8</sup> and *Cln6*<sup>*ncl*</sup> and the beneficial effects of dietary supplementation

### Distinctions and Credentials

Chemical Biology Scholarship, CIHR, Canada, Effective: 09/2008, Ending: 09/2009

National Contest for Life\_NCL Stiftung Hamburg, Germany, Effective: 05/2010, Ending: 10/2011

Novartis Travel Fellowship to ISER Berlin July 2012

**Work Experience****Research Assistant**

10/2009-04/2010

Regensburg University, Regensburg, GERMANY

Under the supervision of Prof. Dr. Karl Kunzelmann I studied electro-physiology of siRNA knocked down elements and their effect on CFTR. Additionally, I improved the western blotting system in the lab. I also studied TMEM16a and anoctamin mutations via western blot.

**Research Assistant**

06/2009-10/2009

Université de Montreal, Montreal, CANADA

Dr. Katherine Borden is a leading scientist in the field of leukemia and is running a nationwide clinical trial on M4/M5 acute myeloid leukemia. I assisted in doing real time PCR on tissue samples collected from patients in the clinical trial as well as western blots by looking for changes in specific markers in these patients.

**Research Assistant**

05/2007 - 08/2007

Cambridge University, Cambridge, U.K.

Under the supervision of Dr. Andrew Peden, I studied the role of VAMPs and SNAREs in post-golgi trafficking. The main objective was to learn how vesicles trafficked to the plasma membrane and back through the lysosomes to the Trans-Golgi Network. This was done by creating mutant cell lines and studying the effects by immunofluorescence.

**Summer Student**

05/2006 - 08/2006

Université de Poitiers, Poitiers, FRANCE

The cystic fibrosis laboratory of Dr. Frederic Becq works on better understanding CF and finding drugs which can correct the trafficking of the mutated protein CFTR. My project consisted of testing the drug Miglustat on different cell lines as well as improving and teaching the western blotting technique to the mostly patch-clamp laboratory.

**Summer Student**

05/2005 - 08/2005

McGill University, Montreal, CANADA

Dr. David Y Thomas had recently started working on CF when I joined the group and started undertaking a major compound screen in search for compounds which could push mutated CFTR to the plasma membrane. I assisted in the screen by western blotting the positive hits and observing effects through confocal microscopy.

**Research Assistant**

10/2004 - 03/2005

Montreal Children's Hospital, Montreal, CANADA

- Working in collaboration with the Toronto's Sick Kids Hospital on The Gene Modifier project
- Conducting thorough research on the medical history of patients with Cystic Fibrosis
- Combining data on Excel databases

**Summer Student Lab Bench Learner**

06/2003 - 08/2003

Montreal Children's Hospital, Montreal, CANADA

Cystic Fibrosis specialist Dr. Larry Lands studies the relationship between CF, chemokines and oxidation in cells. As a learning student I was given a simple project of determining which was the best way to normalize CF assays in papers, either using cell number or protein content.

Through protein assays and cell counting it was concluded that cell number was the best form of normalization. The published abstract is mentioned below.

## Acknowledgements

First and foremost, I would like to thank *Prof. Dr. Thomas Langmann* for giving me the opportunity to work in his lab and be part of his group. Prof. Langmann and I met when I nearly gave up on science and through his patience, kindness, great ideas, encouragement and friendly openness, restored my love and passion for science. He gave me a wonderful Ph.D. project and allowed me to explore my strengths as a scientist and become a better person. I could not envision working with a better supervisor or scientist and I am deeply grateful that our paths crossed when they did.

I would like to thank *Prof. Dr. Stephan Schneuwly* and *Prof. Dr. Rudolf Martini* for being my mentors, committee members and for their support. I would also like to thank *Prof. Dr. Ernst Tamm* for allowing me to work in his lab and sharing his equipment and wonderful lab technicians as well as being the chairman of my thesis committee.

Thank you for *Prof. Dr. Bernhard Weber* for giving me a place to work in the Institute of Human Genetics as well as allowing me to stay and continue my work when my lab moved away.

Thank you to *Dr. Klaus Rüther* for providing the *Cln3<sup>Δex7-8</sup>* and *Cln6<sup>ncl</sup>* mice without which my Ph.D. would not be possible.

Thank you to *Dr. Frank Stehr* from the NCL Stiftung in Hamburg for his endless support, advice and networking. Also, thank you to the NCL Stiftung for supporting part of my work and giving me the wonderful opportunity to work on NCL. Thank you to *Iris Dyck* from the NCL Gruppe Deutschland for supporting the supplementation study and giving me the opportunity to meet children and parents affected by NCL. It really changed my perspective on my research and what it means to be a scientist.

A big thank you for *Prof. Dr. Herbert Jägle* for the ERG experiments and putting up with my endless emails. A special thanks to *Dr. MD Cornelia Volz* for doing the ERG experiments and for playing Sherlock Holmes/Dr. Watson when results and experiments went funny. With her fantastic sense of humour, I always looked forward to her visits in the lab and I am glad we became good friends.

A heartfelt thanks to my lab mates *Alex Aslanidis* and *Dr. Marcus Karlstetter* for being wonderful, funny and helpful colleagues. They made coming to the lab a pleasure. A special thanks to *Yana Walczac* for putting up with me when I had no idea how the lab worked and teaching me so many techniques.

I would like to thank the animal care takers, *Engelbert Meier* and *Stephan Garbowski* for taking such good care of my mice and for their endless friendliness, jokes and occasional coffee.

I would like to extend my sincerest thanks to all the wonderful people in the Institute of Human Genetics for being so kind, helpful and friendly. A particular thanks to *Andrea Milenkovic* and *Kerstin Meier* who would always listen to my dramatic problems of life and lab. A special thanks to secretary *Regina Gellner* for understanding my broken German and helping me with all my paper work when I didn't know what to do.

A special personal thanks to my partner in crime, *Kerstin Rückl*, for being the best technician I have ever met and worked with. She was the first person I went to see when I had any problems or favours. I could not have gone through my last year of Ph.D. sane if she was not with me. She was always in a good mood, always smiling and always up for a new experiment. I will miss you so much. If I ever have a lab of my own, I will steal you!!

I would like to thank my partner and best friend, *Markus Reichold*, for his patience, support and encouragement, not only through my Ph.D., but also through my difficult journey in Germany. He is always there for me with advice, motivation and love, through good and bad times. I could not have made it without him by my side and I am very grateful to have him in my life.

I would like to thank my wonderful, supportive family. My uncles, aunts and cousins have always encouraged me and wished me the best. Special thanks to my cousin *Amber Mirza*, for waking up at 3am when I needed someone to talk to and my brother *Ismaël Mirza*, for being so ambitious and inspiring in everything he does and wants to accomplished.

Finally, I would like to thank my father, *Aftab Mirza* and my mother, *Nancy Chapados*. My father immigrated to Canada when he was a young man, with little education but very big dreams of building an incredible life for his family. I would not be where I am now, if my father didn't work so

hard and long hours to support us through good and bad times. He has always pushed me to do my best and go as far with my education as I possibly can because he believes that education is the most important thing a person can have. My mother has been my rock and my wings throughout my life. She has supported everything I do without question and I cannot think of another person who is braver or stronger than her. I would not be here if she did not push me to be the very best I am every day. Her wisdom and love have guided me through everything in my life, even from an ocean away. I am very grateful that my parents gave me every opportunity I needed to succeed with unconditional love and support.
